Preface

Each of the first two editions of *The Prokaryotes* took a bold step. The first edition, published in 1981, set out to be an encyclopedic, synoptic account of the world of the prokaryotes—a collection of monographic descriptions of the genera of bacteria. The Archaea had not yet been formalized as a group. For the second edition in 1992, the editors made the decision to organize the chapters on the basis of the molecular phylogeny championed by Carl Woese, which increasingly provided a rational, evolutionary basis for the taxonomy of the prokaryotes. In addition, the archaea had by then been recognized as a phylogenetically separate and distinguishable group of the prokaryotes. The two volumes of the first edition had by then expanded to four. The third edition was arguably the boldest step of all. We decided that the material would only be presented electronically. The advantages were obvious and persuasive. There would be essentially unlimited space. There would be no restrictions on the use of color illustrations. Film and animated descriptions could be made available. The text would be hyperlinked to external sources. Publication of chapters would be *seriati*—the edition would no longer have to delay publication until the last tardy author had submitted his or her chapter. Updates and modifications could be made continuously. And, most attractively, a library could place its subscribed copy on its server and make it available easily and cheaply to all in its community. One hundred and seventy chapters have thus far been presented in 16 releases over a six-year period. The virtues and advantages of the online edition have been borne out. But we failed to predict the affection that many have for holding a bound, print version of a book in their hands. Thus, this print version of the third edition shall accompany the online version.

We are now four years into the 21st century. Indulge us then while we comment on the challenges, problems and opportunities for microbiology that confront us.

Moselio Schaechter has referred to the present era of microbiology as its third golden age—the era of “integrative microbiology.” Essentially all microbiologists now speak a common language. So that the boundaries that previously separated subdisciplines from each other have faded: physiology has become indistinguishable from pathogenesis; ecologists and molecular geneticists speak to each other; biochemistry is spoken by all; and—*mirabile dictu!*—molecular biologists are collaborating with taxonomists.

But before these molecular dissections of complex processes can be effective there must be a clear view of the organism being studied. And it is our goal that these chapters in *The Prokaryotes* provide that opportunity.

There is also yet a larger issue. Microbiology is now confronted with the need to understand increasingly complex processes. And the *modus operandi* that has served us so successfully for 150 years—that of the pure culture studied under standard laboratory conditions—is inadequate. We are now challenged to solve problems of multimembered populations interacting with each other and with their environment under constantly variable conditions. Carl Woese has pointed out a useful and important distinction between empirical, methodological reductionism and fundamentalist reductionism. The former has served us well; the latter stands in the way of our further understanding of complex, interacting systems. But no matter what kind of synoptic systems analysis emerges as our way of understanding host–parasite relations, ecology, or multicellular behavior, the understanding of the organism as such is *sine qua non*. And in that context, we are pleased to present to you the third edition of *The Prokaryotes*.

Martin Dworkin
Editor-in-Chief

Foreword

The purpose of this brief foreword is unchanged from the first edition; it is simply to make you, the reader, hungry for the scientific feast that follows. These four volumes on the prokaryotes offer an expanded scientific menu that displays the biochemical depth and remarkable physiological and morphological diversity of prokaryote life. The size of the volumes might initially discourage the unprepared mind from being attracted to the study of prokaryote life, for this landmark assemblage thoroughly documents the wealth of present knowledge. But in confronting the reader with the state of the art, the Handbook also defines where more work needs to be done on well-studied bacteria as well as on unusual or poorly studied organisms.

This edition of *The Prokaryotes* recognizes the almost unbelievable impact that the work of Carl Woese has had in defining a phylogenetic basis for the microbial world. The concept that the ribosome is a highly conserved structure in all cells and that its nucleic acid components may serve as a convenient reference point for relating all living things is now generally accepted. At last, the phylogeny of prokaryotes has a scientific basis, and this is the first serious attempt to present a comprehensive treatise on prokaryotes along recently defined phylogenetic lines. Although evidence is incomplete for many microbial groups, these volumes make a statement that clearly illuminates the path to follow.

There are basically two ways of doing research with microbes. A classical approach is first to define the phenomenon to be studied and then to select the organism accordingly. Another way is to choose a specific organism and go where it leads. The pursuit of an unusual microbe brings out the latent hunter in all of us. The intellectual challenges of the chase frequently test our ingenuity to the limit. Sometimes the quarry repeatedly escapes, but the final capture is indeed a wonderful experience. For many of us, these simple rewards are sufficiently gratifying so that we have chosen to spend our scientific lives studying these unusual creatures. In these endeavors many of the strategies and tools as

well as much of the philosophy may be traced to the Delft School, passed on to us by our teachers, Martinus Beijerinck, A. J. Kluyver, and C. B. van Niel, and in turn passed on by us to our students.

In this school, the principles of the selective, enrichment culture technique have been developed and diversified; they have been a major force in designing and applying new principles for the capture and isolation of microbes from nature. For me, the “organism approach” has provided rewarding adventures. The organism continually challenges and literally drags the investigator into new areas where unfamiliar tools may be needed. I believe that organism-oriented research is an important alternative to problem-oriented research, for new concepts of the future very likely lie in a study of the breadth of microbial life. The physiology, biochemistry, and ecology of the microbe remain the most powerful attractions. Studies based on classical methods as well as modern genetic techniques will result in new insights and concepts.

To some readers, this edition of the *The Prokaryotes* may indicate that the field is now mature, that from here on it is a matter of filling in details. I suspect that this is not the case. Perhaps we have assumed prematurely that we fully understand microbial life. Van Niel pointed out to his students that—after a lifetime of study—it was a very humbling experience to view in the microscope a sample of microbes from nature and recognize only a few. Recent evidence suggests that microbes have been evolving for nearly 4 billion years. Most certainly those microbes now domesticated and kept in captivity in culture collections represent only a minor portion of the species that have evolved in this time span. Sometimes we must remind ourselves that evolution is actively taking place at the present moment. That the eukaryote cell evolved as a chimera of certain prokaryote parts is a generally accepted concept today. Higher as well as lower eukaryotes evolved in contact with prokaryotes, and evidence surrounds us of the complex interactions between eukaryotes and

prokaryotes as well as among prokaryotes. We have so far only scratched the surface of these biochemical interrelationships. Perhaps the legume nodule is a pertinent example of nature caught in the act of evolving the “nitrosome,” a unique nitrogen-fixing organelle. Study of prokaryotes is proceeding at such a fast pace that major advances are occurring yearly. The increase of this edition to four volumes documents the exciting pace of discoveries.

To prepare a treatise such as *The Prokaryotes* requires dedicated editors and authors; the task has been enormous. I predict that the scientific community of microbiologists will again show its appreciation through use of these volumes—such that the pages will become “dog-eared” and worn as students seek basic information for the

hunt. These volumes belong in the laboratory, not in the library. I believe that a most effective way to introduce students to microbiology is for them to isolate microbes from nature, i.e., from their habitats in soil, water, clinical specimens, or plants. *The Prokaryotes* enormously simplifies this process and should encourage the construction of courses that contain a wide spectrum of diverse topics. For the student as well as the advanced investigator these volumes should generate excitement.

Happy hunting!

Volume 5**3. *Proteobacteria***

	Introduction to the Proteobacteria KAREL KERSTERS, PAUL DE VOS, MONIQUE GILLIS, JEAN SWINGS, PETER VAN DAMME and ERKO STACKEBRANDT	3
--	--	---

3.1. *Alpha Subclass*

3.1.1	The Phototrophic Alpha-Proteobacteria JOHANNES F. IMHOFF	41
--------------	---	----

3.1.2	The Genera <i>Prosthecomicrobium</i> and <i>Ancalomicrobium</i> GARY E. OERTLI, CHERYL JENKINS, NAOMI WARD, FREDERICK A. RAINEY, ERKO STACHEBRANDT and JAMES T. STALEY	65
3.1.3	Dimorphic Prosthecate Bacteria: The Genera <i>Caulobacter</i> , <i>Asticcacaulis</i> , <i>Hyphomicrobium</i> , <i>Pedomicrobium</i> , <i>Hyphomonas</i> and <i>Thiodendron</i> JEANNE S. POINDEXTER	72
3.1.4	The Genus <i>Agrobacterium</i> ANN G. MATTHYSSE	91
3.1.5	The Genus <i>Azospirillum</i> ANTON HARTMANN and JOSE IVO BALDANI	115
3.1.6	The Genus <i>Herbaspirillum</i> MICHAEL SCHMID, JOSE IVO BALDANI and ANTON HARTMANN	141
3.1.7	The Genus <i>Beijerinckia</i> JAN HENDRICK BECKING	151
3.1.8	The Family Acetobacteraceae: The Genera <i>Acetobacter</i> , <i>Acidomonas</i> , <i>Asaia</i> , <i>Gluconacetobacter</i> , <i>Gluconobacter</i> , and <i>Kozakia</i> KAREL KERSTERS, PUSPITA LISDIYANTI, KAZUO KOMAGATA and JEAN SWINGS	163
3.1.9	The Genus <i>Zymomonas</i> HERMANN SAHM, STEPHANIE BRINGER-MEYER and GEORG A. SPRENGER	201
3.1.10	The Manganese-Oxidizing Bacteria KENNETH H. NEALSON	222
3.1.11	The Genus <i>Paracoccus</i> DONOVAN P. KELLY, FREDERICK A. RAINEY and ANN P. WOOD	232
3.1.12	The Genus <i>Phenylobacterium</i> JÜRGEN EBERSPÄCHER and FRANZ LINGENS	250
3.1.13	<i>Methylobacterium</i> PETER N. GREEN	257
3.1.14	The Methanotrophs—The Families Methylococcaceae and Methylocystaceae JOHN P. BOWMAN	266
3.1.15	The Genus <i>Xanthobacter</i> JÜRGEN WIEGEL	290
3.1.16	The Genus <i>Brucella</i> EDGARDO MORENO and IGNACIO MORIYÓN	315
3.1.17	Introduction to the Rickettsiales and Other Intracellular Prokaryotes DAVID N. FREDRICKS	457
3.1.18	The Genus <i>Bartonella</i> MICHAEL F. MINNICK and BURT E. ANDERSON	467

3.1.19	The Order Rickettsiales XUE-JIE YU and DAVID H. WALKER	493
3.1.20	The Genus <i>Coxiella</i> ROBERT A. HEINZEN and JAMES E. SAMUEL	529
3.1.21	The Genus <i>Wolbachia</i> MARKUS RIEGLER and SCOTT L. O'NEILL	547
3.1.22	Aerobic Phototrophic Proteobacteria VLADIMIR V. YURKOV	562
3.1.23	The Genus <i>Seliberia</i> JEAN M. SCHMIDT and JAMES R. SWAFFORD	585
3.2.	<i>Beta Subclass</i>	
3.2.1	The Phototrophic Betaproteobacteria JOHANNES F. IMHOFF	593
3.2.2	The <i>Neisseria</i> DANIEL C. STEIN	602
3.2.3	The Genus <i>Bordetella</i> ALISON WEISS	648
3.2.4	<i>Achromobacter</i> , <i>Alcaligenes</i> and Related Genera HANS-JÜRGEN BUSSE and ANDREAS STOLZ	675
3.2.5	The Genus <i>Spirillum</i> NOEL R. KRIEG	701
3.2.6	The Genus <i>Aquaspirillum</i> BRUNO POT, MONIQUE GILLIS and JOZEF DE LEY	710
3.2.7	<i>Comamonas</i> ANNE WILLEMS and PAUL DE VOS	723
3.2.8	The Genera <i>Chromobacterium</i> and <i>Janthinobacterium</i> MONIQUE GILLIS and JOZEF DE LEY	737
3.2.9	The Genera <i>Phyllobacterium</i> and <i>Ochrobactrum</i> JEAN SWINGS, BART LAMBERT, KAREL KERSTERS and BARRY HOLMES	747
3.2.10	The Genus <i>Derxia</i> JAN HENDRICK BECKING	751
3.2.11	The Genera <i>Leptothrix</i> and <i>Sphaerotilus</i> STEFAN SPRING	758
3.2.12	The Lithoautotrophic Ammonia-Oxidizing Bacteria HANS-PETER KOOPS, ULRIKE PURKHOLD, ANDREAS POMMERENING-RÖSER, GABRIELE TIMMERMANN and MICHAEL WAGNER	778

3.2.13	The Genus <i>Thiobacillus</i> LESLEY A. ROBERTSON and J. GIJS KUENEN	812
3.2.14	The Genera <i>Simonsiella</i> and <i>Alysiella</i> BRIAN P. HEDLUND and DAISY A. KUHN	828
3.2.15	<i>Eikenella corrodens</i> and Closely Related Bacteria EDWARD J. BOTTONE and PAUL A. GRANATO	840
3.2.16	The Genus <i>Burkholderia</i> DONALD E. WOODS and PAMELA A. SOKOL	848
3.2.17	The Nitrite-Oxidizing Bacteria AHARON ABELIOVICH	861
3.2.18	The Genera <i>Azoarcus</i> , <i>Azovibrio</i> , <i>Azospira</i> and <i>Azonexus</i> BARBARA REINHOLD-HUREK and THOMAS HUREK	873
Index		893

Volume 6

3. *Proteobacteria*

3.3. *Gamma Subclass*

3.3.1	New Members of the Family Enterobacteriaceae J. MICHAEL JANDA	5
3.3.2	Phylogenetic Relationships of Bacteria with Special Reference to Endosymbionts and Enteric Species M. PILAR FRANCINO, SCOTT R. SANTOS and HOWARD OCHMAN	41
3.3.3	The Genus <i>Escherichia</i> RODNEY A. WELCH	60
3.3.4	The Genus <i>Edwardsiella</i> SHARON L. ABBOTT and J. MICHAEL JANDA	72
3.3.5	The Genus <i>Citrobacter</i> DIANA BORENSHTEIN and DAVID B. SCHAUER	90
3.3.6	The Genus <i>Shigella</i> YVES GERMANI and PHILIPPE J. SANSONETTI	99
3.3.7	The Genus <i>Salmonella</i> CRAIG D. ELLERMEIER and JAMES M. SLAUCH	123
3.3.8	The Genus <i>Klebsiella</i> SYLVAIN BRISSE, FRANCINE GRIMONT and PATRICK A. D. GRIMONT	159

3.3.9	The Genus <i>Enterobacter</i> FRANCINE GRIMONT and PATRICK A. D. GRIMONT	197
3.3.10	The Genus <i>Hafnia</i> MEGAN E. MCBEE and DAVID B. SCHAUER	215
3.3.11	The Genus <i>Serratia</i> FRANCINE GRIMONT and PATRICK A. D. GRIMONT	219
3.3.12	The Genera <i>Proteus</i> , <i>Providencia</i> , and <i>Morganella</i> JIM MANOS and ROBERT BELAS	245
3.3.13	<i>Y. enterocolitica</i> and <i>Y. pseudotuberculosis</i> ELISABETH CARNIEL, INGO AUTENRIETH, GUY CORNELIS, HIROSHI FUKUSHIMA, FRANÇOISE GUINET, RALPH ISBERG, JEANNETTE PHAM, MICHAEL PRENTICE, MICHEL SIMONET, MIKAEL SKURNIK and GEORGES WAUTERS	270
3.3.14	<i>Yersinia pestis</i> and Bubonic Plague ROBERT BRUBAKER	399
3.3.15	<i>Erwinia</i> and Related Genera CLARENCE I. KADO	443
3.3.16	The Genera <i>Photorhabdus</i> and <i>Xenorhabdus</i> NOEL BOEMARE and RAYMOND AKHURST	451
3.3.17	The Family Vibrionaceae J. J. FARMER, III	495
3.3.18	The Genera <i>Vibrio</i> and <i>Photobacterium</i> J. J. FARMER, III and F. W. HICKMAN-BRENNER	508
3.3.19	The Genera <i>Aeromonas</i> and <i>Plesiomonas</i> J. J. FARMER, III, M. J. ARDUINO and F. W. HICKMAN-BRENNER	564
3.3.20	The Genus <i>Alteromonas</i> and Related Proteobacteria VALERY V. MIKHAILOV, LYUDMILA A. ROMANENKO and ELENA P. IVANOVA	597
3.3.21	Nonmedical: <i>Pseudomonas</i> EDWARD R. B. MOORE, BRIAN J. TINDALL, VITOR A. P. MARTINS DOS SANTOS, DIETMAR H. PIEPER, JUAN-LUIS RAMOS and NORBERTO J. PALLERONI	646
3.3.22	<i>Pseudomonas aeruginosa</i> TIMOTHY L. YAHR and MATTHEW R. PARSEK	704
3.3.23	Phytopathogenic Pseudomonads and Related Plant-Associated Pseudomonads MILTON N. SCHROTH, DONALD C. HILDEBRAND and NICKOLAS PANOPOULOS	714
3.3.24	<i>Xylophilus</i> ANNE WILLEMS and MONIQUE GILLIS	741

3.3.25	The Genus <i>Acinetobacter</i> KEVIN TOWNER	746
3.3.26	The Family Azotobacteraceae JAN HENDRICK BECKING	759
3.3.27	The Genera <i>Beggiatoa</i> and <i>Thioploca</i> ANDREAS TESKE and DOUGLAS C. NELSON	784
3.3.28	The Family Halomonadaceae DAVID R. ARAHAL and ANTONIO VENTOSA	811
3.3.29	The Genus <i>Deleya</i> KAREL KERSTERS	836
3.3.30	The Genus <i>Frateuria</i> JEAN SWINGS	844
3.3.31	The Chromatiaceae JOHANNES F. IMHOFF	846
3.3.32	The Family Ectothiorhodospiraceae JOHANNES F. IMHOFF	874
3.3.33	<i>Oceanospirillum</i> and Related Genera JOSÉ M. GONZÁLEZ and WILLIAM B. WHITMAN	887
3.3.34	<i>Serpens flexibilis</i> : An Unusually Flexible Bacterium ROBERT B. HESPELL	916
3.3.35	The Genus <i>Psychrobacter</i> JOHN P. BOWMAN	920
3.3.36	The Genus <i>Leucothrix</i> THOMAS D. BROCK	931
3.3.37	The Genus <i>Lysobacter</i> HANS REICHENBACH	939
3.3.38	The Genus <i>Moraxella</i> JOHN P. HAYS	958
3.3.39	<i>Legionella</i> Species and Legionnaire's Disease PAUL H. EDELSTEIN and NICHOLAS P. CIANCOTTO	988
3.3.40	The Genus <i>Haemophilus</i> DORAN L. FINK and JOSEPH W. ST. GEME, III	1034
3.3.41	The Genus <i>Pasteurella</i> HENRIK CHRISTENSEN and MAGNE BISGAARD	1062
3.3.42	The Genus <i>Cardiobacterium</i> SYDNEY M. HARVEY and JAMES R. GREENWOOD	1091

3.3.43	The Genus <i>Actinobacillus</i> JANET I. MACINNES and EDWARD T. LALLY	1094
3.3.44	The Genus <i>Francisella</i> FRANCIS NANO and KAREN ELKINS	1119
3.3.45	Ecophysiology of the Genus <i>Shewanella</i> KENNETH H. NEALSON and JAMES SCOTT	1133
3.3.46	The Genus <i>Nevskia</i> HERIBERT CYPIONKA, HANS-DIETRICH BABENZIEN, FRANK OLIVER GLÖCKNER and RUDOLF AMANN	1152
3.3.47	The Genus <i>Thiomargarita</i> HEIDE N. SCHULZ	1156
Index		1165

Volume 7

3.	<i>Proteobacteria</i>	
3.4	<i>Delta Subclass</i>	
3.4.1	The Genus <i>Pelobacter</i> BERNHARD SCHINK	5
3.4.2	The Genus <i>Bdellovibrio</i> EDOUARD JURKEVITCH	12
3.4.3	The Myxobacteria LAWRENCE J. SHIMKETS, MARTIN DWORKIN and HANS REICHENBACH	31
3.5.	<i>Epsilon Subclass</i>	
3.5.1	The Genus <i>Campylobacter</i> TRUDY M. WASSENAAR and DIANE G. NEWELL	119
3.5.2	The Genus <i>Helicobacter</i> JAY V. SOLNICK, JANI L. O'ROURKE, PETER VAN DAMME and ADRIAN LEE	139
3.5.3	The Genus <i>Wolinella</i> JÖRG SIMON, ROLAND GROSS, OLIVER KLIMMEK and ACHIM KRÖGER	178
4.	<i>Spirochetes</i>	
4.1	Free-Living Saccharolytic Spirochetes: The Genus <i>Spirochaeta</i> SUSAN LESCHINE, BRUCE J. PASTER and ERCOLE CANALE-PAROLA	195

4.2	The Genus <i>Treponema</i> STEVEN J. NORRIS, BRUCE J. PASTER, ANNETTE MOTER and ULF B. GÖBEL	211
4.3	The Genus <i>Borrelia</i> MELISSA J. CAIMANO	235
4.4	The Genus <i>Leptospira</i> BEN ADLER and SOLLY FAINE	294
4.5	Termite Gut Spirochetes JOHN A. BREZNAK and JARED R. LEADBETTER	318
4.6	The Genus <i>Brachyspira</i> THADDEUS B. STANTON	330
5.	<i>Chlorobiaceae</i>	
5.1	The Family Chlorobiaceae JÖRG OVERMANN	359
6.	<i>Bacteroides and Cytophaga Group</i>	
6.1	The Medically Important <i>Bacteroides</i> spp. in Health and Disease C. JEFFREY SMITH, EDSON R. ROCHA and BRUCE J. PASTER	381
6.2	The Genus <i>Porphyromonas</i> FRANK C. GIBSON and CAROLINE ATTARDO GENCO	428
6.3	An Introduction to the Family Flavobacteriaceae JEAN-FRANÇOIS BERNARDET and YASUYOSHI NAKAGAWA	455
6.4	The Genus <i>Flavobacterium</i> JEAN-FRANÇOIS BERNARDET and JOHN P. BOWMAN	481
6.5	The Genera <i>Bergeyella</i> and <i>Weeksella</i> CELIA J. HUGO, BRITA BRUUN and PIET J. JOOSTE	532
6.6	The Genera <i>Flavobacterium</i> , <i>Sphingobacterium</i> and <i>Weeksella</i> BARRY HOLMES	539
6.7	The Order Cytophagales HANS REICHENBACH	549
6.8	The Genus <i>Saprospira</i> HANS REICHENBACH	591
6.9	The Genus <i>Haliscomenobacter</i> EPPE GERKE MULDER and MARIA H. DEINEMA	602
6.10	<i>Sphingomonas</i> and Related Genera DAVID L. BALKWILL, J. K. FREDRICKSON and M. F. ROMINE	605

6.11	The Genera <i>Empedobacter</i> and <i>Myroides</i> CELIA J. HUGO, BRITA BRUUN and PIET J. JOOSTE	630
6.12	The Genera <i>Chryseobacterium</i> and <i>Elizabethkingia</i> JEAN-FRANÇOIS BERNARDET, CELIA J. HUGO and BRITA BRUUN	638
6.13	The Marine Clade of the Family Flavobacteriaceae: The Genera <i>Aequorivita</i> , <i>Arenibacter</i> , <i>Cellulophaga</i> , <i>Croceibacter</i> , <i>Formosa</i> , <i>Gelidibacter</i> , <i>Gillisia</i> , <i>Maribacter</i> , <i>Mesonina</i> , <i>Muricauda</i> , <i>Polaribacter</i> , <i>Psychroflexus</i> , <i>Psychroserpens</i> , <i>Robiginitalea</i> , <i>Salegentibacter</i> , <i>Tenacibaculum</i> , <i>Ulvibacter</i> , <i>Vitellibacter</i> and <i>Zobellia</i> JOHN P. BOWMAN	677
6.14	Capnophilic Bird Pathogens in the Family Flavobacteriaceae: <i>Riemerella</i> , <i>Ornithobacterium</i> and <i>Coenonia</i> PETER VAN DAMME, H. M. HAFEZ and K. H. HINZ	695
6.15	The Genus <i>Capnocytophaga</i> E. R. LEADBETTER	709
6.16	The Genera <i>Rhodothermus</i> , <i>Thermonema</i> , <i>Hymenobacter</i> and <i>Salinibacter</i> AHARON OREN	712
7.	<i>Chlamydia</i>	
7.1	The Genus <i>Chlamydia</i> —Medical MURAT V. KALAYOGLU and GERALD I. BYRNE	741
8.	<i>Planctomyces and Related Bacteria</i>	
8.1	The Order Planctomycetales, Including the Genera <i>Planctomyces</i> , <i>Pirellula</i> , <i>Gemmata</i> and <i>Isosphaera</i> and the Candidatus Genera <i>Brocadia</i> , <i>Kuenenia</i> and <i>Scalindua</i> NAOMI WARD, JAMES T. STALEY, JOHN A. FUERST, STEPHEN GIOVANNONI, HEINZ SCHLESNER and ERKO STACHEBRANDT	757
9.	<i>Thermus</i>	
9.1	The Genus <i>Thermus</i> and Relatives MILTON S. DA COSTA, FREDERICK A. RAINEY and M. FERNANDA NOBRE	797
10.	<i>Chloroflexaceae and Related Bacteria</i>	
10.1	The Family Chloroflexaceae SATOSHI HANADA and BEVERLY K. PIERSON	815
10.2	The Genus <i>Thermoleophilum</i> JEROME J. PERRY	843
10.3	The Genus <i>Thermomicrobium</i> JEROME J. PERRY	849

10.4	The Genus <i>Herpetosiphon</i> NATUSCHKA LEE and HANS REICHENBACH	854
11.	<i>Verrucomicrobium</i>	
11.1	The Phylum Verrucomicrobia: A Phylogenetically Heterogeneous Bacterial Group HEINZ SCHLESNER, CHERYL JENKINS and JAMES T. STALEY	881
12.	<i>Thermotogales</i>	
12.1	Thermotogales ROBERT HUBER and MICHAEL HANNIG	899
13.	<i>Aquificales</i>	
13.1	Aquificales ROBERT HUBER and WOLFGANG EDER	925
14.	<i>Phylogenetically Unaffiliated Bacteria</i>	
14.1	Morphologically Conspicuous Sulfur-Oxidizing Eubacteria JAN W. M. LA RIVIÈRE and KARIN SCHMIDT	941
14.2	The Genus <i>Propionigenium</i> BERNHARD SCHINK	955
14.3	The Genus <i>Zoogloea</i> PATRICK R. DUGAN, DAPHNE L. STONER and HARVEY M. PICKRUM	960
14.4	Large Symbiotic Spirochetes: <i>Clevelandina</i> , <i>Cristispira</i> , <i>Diplocalyx</i> , <i>Hollandina</i> and <i>Pillotina</i> LYNN MARGULIS and GREGORY HINKLE	971
14.5	<i>Streptobacillus moniliformis</i> JAMES R. GREENWOOD and SYDNEY M. HARVEY	983
14.6	The Genus <i>Toxothrix</i> PETER HIRSCH	986
14.7	The Genus <i>Gallionella</i> HANS H. HANERT	990
14.8	The Genera <i>Caulococcus</i> and <i>Kusnezovia</i> JEAN M. SCHMIDT and GEORGI A. ZAVARZIN	996
14.9	The Genus <i>Brachyarcus</i> PETER HIRSCH	998

14.10	The Genus <i>Pelosigma</i> PETER HIRSCH	1001
14.11	The Genus <i>Siderocapsa</i> (and Other Iron- and Maganese-Oxidizing Eubacteria) HANS H. HANERT	1005
14.12	The Genus <i>Fusobacterium</i> TOR HOFSTAD	1016
14.13	Prokaryotic Symbionts of Amoebae and Flagellates KWANG W. JEON	1028
Index		1039

The Archaea: A Personal Overview of the Formative Years

RALPH S. WOLFE

“—a new scientific truth does not triumph by convincing its opponents and making them see the light, but rather because its opponents eventually die, and a new generation grows up that is familiar with it.” Max Planck

The year 2002 marks the 25th anniversary of the discovery of the Archaea. Data to support this discovery were presented in the *Proceedings of the National Academy of Science* of October 1977 (Fox et al., 1977). However, most people learned about methanogens, “a third form of life,” from the front pages of their newspapers on Thursday, November 3, 1977, the day the *PNAS* issue was available. The National Science Foundation (NSF) and the National Aeronautics and Space Administration (NASA) supported the research of Carl Woese and were pleased to sponsor and receive publicity for the press release he presented. When discussing the importance of the discovery with reporters prior to the press release, Woese had difficulty communicating in scientific terms that they could understand, until he hit upon the phrase, “a third form of life.” They could relate to this phrase, and it became prominent in their articles. Methanogens, though prokaryotes, were only distantly related to other prokaryotes.

The immediate response of the scientific community to the press release was negative with disbelief and much hostility, especially among microbiologists. Scientists were suspicious of scientific publication in newspapers, and only a very few were familiar with the use of 16S rRNA oligonucleotides to define relationships among organisms. Among the phone calls that I received the morning of November 3, the one by S. E. Luria was the most civil and free of four-letter words. Luria was a Professor of Microbiology, when I joined the Department at Illinois in 1953 and had later moved to MIT. Luria: “Ralph, you must dissociate yourself from this nonsense, or you’re going to ruin your career!” “But, Lu, the data are solid and support the conclusions: they are in the current issue of *PNAS*.” Luria: “Oh yes, my issue just arrived.” “If you would like to discuss the paper after you have had a chance to look at it, give me a ring.” He did not call again.

I wanted to crawl under something and hide. Fortunately I was able to escape the hostility and left graduate students to cope, because my wife and I were leaving for Philadelphia to help celebrate her father’s 90th birthday. We collected a few newspapers in airports. Carl was on the front page of the *New York Times* with his Adidas-clad feet prominently displayed on his desk. Much later he would say, “You know, Adidas never offered me a contract.” In Philadelphia, I explained in dismay to my father-in-law what my colleague had done, and his response was: “You know, in my long life I have observed something, if you don’t overstate your case, no one will listen.” I felt better. However, in hindsight, the press release polarized the scientific community, and the majority refused to read the literature, delaying acceptance of the Archaeobacteria for perhaps a decade. The discovery of the Archaea resulted from the intersection of two independent lines of research; the culmination of the informational-macromolecule line was the research of Carl Woese, whereas the biochemistry of methanogenesis was pursued by my research group.

Informational Macromolecules

This line began with the publications of Sanger and coworkers (Sanger and Tuppy, 1951; Sanger and Thompson, 1953), who showed each amino acid in the two chains of insulin occupies a precise position in the protein molecule. This discovery had enormous implications for genetics and for the emerging area of molecular biology. By the 1960s, insulin molecules from various animal species had been sequenced, and it was apparent that insulin from different species possessed variations in the sequence of certain amino acids. Zuckerkandl and Pauling (1965) pointed out that these differences could be used to determine the relationship among the molecules, and hence, the organisms from which they were obtained; macromolecules which showed only minor sequence changes were closely related, whereas those with larger differences were more distantly related. The next macromolecules to be sequenced were

other small proteins, for example, cytochromes, but the limitations of protein molecules to study relatedness among organisms soon became apparent.

In the early 1960s, Carl Woese's study of the ribosome convinced him that this structure was highly conserved. He reasoned that because the ribosome is of ancient origin, is universally distributed, and is functionally equivalent in all living cells, it would be the ideal structure to use for study of evolution. In addition, the ribosome has only one function, translation of the genetic code into the amino acid sequence of a protein, and may be somewhat "insulated" from the variables of phenotypic encounters. Then, Sanger et al. (1965) published a method for a two-dimensional (2-D) fractionation of radioactive nucleotides, which could be used to sequence RNA. Woese's seminal insight was to recognize that ribosomal RNA was the ideal molecule to follow evolution to very ancient events. He modified the Sanger RNA sequencing technique and explored the use of ribosomal 5S, 16S, and 23S rRNA. He chose 16S rRNA as a "statistical ensemble" of 1540 monomers that would allow investigations of organisms to reach the very root of the tree of life. Carl Woese was alone in developing the use of ^{32}P -labelled oligonucleotides from T_1 endonuclease digests of 16S rRNA to generate a similarity coefficient that could be used to determine the relatedness of organisms (Sogin et al., 1972; Pechman and Woese, 1972).

I was fascinated by this new approach, for as a graduate student I had been prejudiced against "bug sorting" and its tenuous results by my professor, and I resolved never to get involved in taxonomy with its constant reshuffling and renaming of species. But here was something I could believe in, for it had a sense of permanence. I was especially impressed by results of Woese's initial study of the genus, *Bacillus* (Woese et al., 1976). I became a believer. Today with greatly improved technology, data can be generated in one day that took Woese months to do in 1969. By 1976, Woese had obtained the 16S rRNA similarity coefficients of 60 microbes, representing a wide diversity.

Biochemistry of Methanogenesis

This line had an early beginning with the experiments of Alessandro Volta in 1776 which showed that the gas produced by decaying vegetable residues in sediments was combustible; its identity as methane came a century later, and definitive experiments with methanogenic bacteria came with the isolation of *Methanobacillus omelianskii* (Barker, 1936; Barker, 1940). For

over 20 years after 1936, Barker's laboratory was the leader in studying methanogens, and many observations led him to conclude that these organisms, though morphologically diverse, had a common physiology. In 1961, I was attracted to and began to investigate the unexplored biochemistry of methanogenesis. An enzymically active cell extract had not been prepared. Because of the formidable challenges in cultivating these organisms, knowledge of their biochemistry lagged decades behind other organisms.

Barker's culture of *M. omelianskii* was mass cultured, and the first cell-free formation of methane was obtained (Wolin et al., 1963). In collaboration with Bryant and Wolin, Barker's culture of *M. omelianskii* was found to be a symbiotic association of two organisms, i.e., interspecies hydrogen transfer had been discovered (Bryant et al., 1967). The methanogenic organism from the mixed culture oxidized hydrogen and reduced carbon dioxide to methane. My laboratory developed a technology for mass culture of the organism on hydrogen and carbon dioxide (Bryant et al., 1968), which was scaled up to the 200-liter level. With kilogram quantities of cells available, the first unique coenzyme of methanogenesis was discovered and named "coenzyme M" (McBride and Wolfe, 1971). Its structure was determined, and its methylated active form was synthesized (Taylor and Wolfe, 1974a). The unusual coenzyme was found to be a "vitamin" required by a methanogen from the cow's rumen, *Methanobacterium ruminantium* (Taylor et al., 1974b). To assay this vitamin, this organism was grown via a new procedure, the Balch modification of the Hungate technique, involving use of a pressurized atmosphere of hydrogen and carbon dioxide (Balch and Wolfe, 1976). After exhaustive analyses, CoM was found nowhere else in nature. A second unique coenzyme (Eirich et al., 1978), the blue-green fluorescent deazaflavin, F_{420} , was found to be the coenzyme for formic dehydrogenase (Tzeng et al., 1975). By 1976, evidence for other unique coenzymes was in hand in my laboratory.

Discovery of the Archaea

The simple method of growing methanogenic cells in an anaerobic pressurized atmosphere of hydrogen and carbon dioxide was pivotal to the discovery of the Archaea, for hydrogen and carbon dioxide could be replenished with safe containment of high levels of ^{32}P and without exposure of cells to oxygen or contamination. After analysis of the 2-D chromatographic pattern of the T_1 endonuclease digestion fragments from the 16S RNA of the first methanogen, I

asked about the results. Woese was puzzled, for the pattern was unlike any he had seen; he could only conclude that: "Somehow we must have isolated the wrong RNA." So the experiment was repeated with special care, and this time, his response was: "Wolfe, these methanogens are not bacteria." "Of course they are Carl; they look like bacteria." "They are not related to any bacteria I've seen." Because Woese had spent nearly 10 years alone developing the method and analyzing the 2-D chromatographic patterns of T₁ endonuclease digestion patterns of ³²P-labelled 16S rRNA from 60 different bacteria, he was easily able to discern that methanogens were different! But what should the group be called?

In November 1977, Woese and Fox proposed that ribosomal RNA sequence characterization could be used to define three "aboriginal lines of descent" (Woese and Fox, 1977). One line, the typical bacteria, was designated "eubacteria." "Archaeobacteria" was proposed as a name for the methanogen line, and the term "urkaryotes" was proposed for the cytoplasmic component of eukaryotic cells. So the methanogens were Archaeobacteria. The name Archaeobacteria was suggested by David Nanney. In a way, the term was unfortunate because the case was being made that the methanogens were "old" (i.e., represented a very ancient divergence in evolution), so that they were no more related to bacteria than to eukaryotes. On the other hand, they were bacteria. (Over a decade later, Woese, Kandler, and Wheelis would propose the name "Archaea" for the Archaeobacteria [Woese et al., 1990]. By that time, much evidence had accumulated showing the Archaea clearly belonged on the eukaryotic line of descent, and it would be less confusing if the word "bacteria" in Archaeobacteria was deleted.)

All of the available methanogens in pure culture were obtained and subjected to 16S rRNA analysis. The results were startling (Fox et al., 1977); none of the species was related to typical bacteria, but they fell into natural groups. Additionally, the unusual biochemistry of methanogens now assumed importance. Methanogens are the only organisms that produce methane as their metabolic product, and they do so by a biochemistry that employs unique enzymes and coenzymes. So, the initial concept that methanogens were different rested on 16S rRNA analysis and was supported by unique biochemistry. While these studies were underway, it occurred to me that, if methanogens were so different in these aspects, they should show differences in other areas. So, I wrote to Otto Kandler in November 1976 explaining that Carl Woese had determined methanogens to be only distantly related to bacteria and asked him whether he would be interested in determining the structure

of the cell walls of methanogens, which we could send to him. He was enthusiastic about the project for his laboratory had been studying the cell walls of diverse bacteria including *Halococcus morrhuae* (Schleifer and Kandler, 1972; Steber and Schleifer, 1975) and *Methanosarcina* (Kandler and Hippe, 1977) which were shown to lack peptidoglycan. This letter would have an effect far beyond its simple question, for Kandler found a gold mine and became convinced that the Archaeobacterial concept represented a major turning point for prokaryotic phylogeny. In 1977, he made a trip to Urbana, Illinois, to obtain the most direct information. He became convinced that German microbiologists should begin serious work on the Archaeobacteria. His laboratory soon showed that species of *Methanobacterium* lacked typical peptidoglycan (murein) cell walls, known to be a characteristic of all bacteria. Other species of methanogens had no peptidoglycan derivatives at all (Kandler and König, 1978), and when the project was complete, Kandler's laboratory had shown that there were as many variations in the cell walls of methanogens as in all bacteria combined! This was a breakthrough—a third pillar to support the concept that the methanogens were different.

The year 1978 was eventful in fine tuning the concept that methanogenic bacteria (10 species) were so distantly related to typical bacteria that they should be considered as a distinct phylogenetic group, the Archaeobacteria. Tornabene et al. (1978) investigated the lipids of *Methanobacterium thermoautotrophicum* and found that phytanyl-glycerol ethers and squalenes were major lipid components. A fourth pillar to support the Archaeobacterial concept was in place. This unusual lipid composition was similar to that of *Halobacterium cutirubrum* reported by Kates et al. (1965) and Tornabene et al. (1969). However, the discovery of these unusual lipids in *Halobacterium* had not created wide interest at the time of publication, for their possession was largely perceived to be a consequence of adaptation to growth in saturated salt environments. Similarly, organisms previously isolated from thermoacidic aquatic environments, *Sulfolobus* and *Thermoplasma* summarized by Brock (1978), had been shown to contain only negligible amounts of ester-linked lipids (Langworthy et al., 1972; DeRosa et al., 1975; DeRosa et al., 1976). Cell walls of *Sulfolobus* had been shown by Brock et al. (1972) to be deficient in peptidoglycan, and of course, species of mycoplasma were known to have only a protein covering. Again it was presumed that perhaps the lipids and lack of peptidoglycan were related (somehow) to growth in hot acidic environments. Then Woese, Magrum, and Fox brought it all together in an article entitled "Archaeobacte-

ria" (Woese et al., 1978), and expanded the concept to include the methanogens, extreme halophiles, and thermoacidophiles, the common factors being: 1) the possession of characteristic ribosomal RNAs and tRNAs; 2) the absence of murein cell walls; and 3) the presence of ether-linked lipids in phytanyl chains.

In 1978, Zillig and coworkers began to report results of experiments on the remarkably similar component patterns of the DNA-dependent RNA polymerases of Archaeobacteria and eukaryotes (Zillig et al., 1978; Zillig et al., 1979; Stetter et al., 1980; Sturm et al., 1980). In addition, the Archaeobacterial polymerases showed characteristic eukaryotic resistance against the inhibitors rifampicin, streptolydigin, and α -amanitin. Because the DNA-dependent RNA polymerases of eubacteria have the standard four-component composition $\beta'\beta\alpha\sigma$, it was assumed that all prokaryotes would be similar. However, the Archaeobacterial RNA polymerases contained 7 to 12 different components, showing a pattern similar to *Saccharomyces cerevisiae*. The results summarized by Zillig et al. (1985) were so astounding that many viewed them as conclusive evidence, alone, that Archaeobacteria indeed represented a third domain of life. Another pillar to support the Archaeobacteria was in place.

In 1979, an interesting observation was made in the laboratory of Friedrich Klink by M. Kessel. He found that in vitro protein synthesis by halobacterial preparations was inhibited by diphtheria toxin (Kessel and Klink, 1980). These studies were extended to 18 Archaeobacteria (Kessel and Klink, 1982). The state of the field was summarized by Klink (1985). The Archaeobacteria have an elongation apparatus in the ribosome that is distinct from those of typical bacteria and eukaryotes. All Archaeobacteria contain a structural domain in elongation factor-2 (EF-2) that renders it a substrate for diphtheria toxin. Archaeobacterial EF-2 is highly specific for Archaeobacterial ribosomes and does not work with ribosomes from bacteria or eukaryotes. These experiments attracted wide interest because they exploded the perceived dogma that all prokaryotes are insensitive to the diphtheria toxin; so another pillar to support the Archaeobacterial concept was in place.

However, the concept of the Archaeobacteria, outside of a very few believers, was not embraced by the microbiological community. So in 1978, I suggested to William Balch, a graduate student in my laboratory, that we gather together in a review article all of the evidence in support of methanogens as Archaeobacteria. He did a magnificent job dedicating his considerable talents to the task and working closely with Woese. With the dedicated help of Marvin Bryant, a new

classification of methanogens based on 16S rRNA was included in the article. The review displayed eloquently the power of 16S rRNA to show the relatedness of organisms, i.e., a poorly understood group of methanogens as diverse as all bacteria combined was finally organized into a phylogeny that made sense. Marv Bryant, the world authority on methanogens, pronounced the results "beautiful, beautiful." The four types of cell walls, the C_{20} diphytanyl glycerol diethers, the C_{40} dibiphytanyl diglycerol tetraethers, and $C_{30}H_{30}$ squalene of the neutral lipid fraction were Archaeobacterial. The structure and function of coenzyme M and coenzyme F_{420} had been determined (Taylor and Wolfe, 1974a; Taylor et al., 1974b; Eirich, L. D., et al., 1978; Tzeng et al., 1975) and were clearly unique to the biochemistry of methanogenesis. Although initially the uniqueness of these coenzymes supported the Archaeobacterial concept, it soon appeared that they were not found at the time in known species of extreme halophiles or thermoacidophiles and so were a general characteristic of methanogens only. In addition to ribosomal RNA, transfer RNAs of methanogens were found to be unique; they do not contain the universal common arm sequence. The review, "Methanogens: Reevaluation of a unique biological group," appeared in the June 1979 issue of *Microbiological Reviews* (Balch et al., 1979) and was received with respect by the microbiological community. The work attracted the interest of a number of new investigators to the Archaeobacteria.

Because Rolf Thauer had close contact with the German Forschungsgemeinschaft, Kandler asked him in March 1978 to think about a proposal for funds to initiate a Schwerpunkt-program for research on methanogens and other Archaeobacteria. Thauer agreed to head the Schwerpunkt, but to avoid controversy, they decided not to use the term "Archaeobacteria" in their grant application, since this term was not well accepted at the time. The DFG-Schwerpunkt-program, "Methanogene Bakterien," was funded in 1979. Despite the title, research on other Archaeobacteria was encouraged. The initial investigators included J. Andreesen (Göttingen), A. Bacher (Garching), G. Diekert (Marburg/Stuttgart), G. Fuchs (Marburg/Ulm), G. Gottschalk (Göttingen), O. Kandler (München), A. Klein (Marburg), H. König (Regensburg/Ulm), P. Scherer (Jülich/Weihenstephan), P. Schönheit (Marburg/Berlin), R. Thauer (Marburg), J. Winter (Regensburg). Kandler was the instigating force in the initiation of this effort, which stands in stark contrast to the rejection of or ambivalence toward the Archaeobacterial concept by microbiologists in other countries, who were quite content with the entrenched taxonomy of the time.

The Schwerpunkt paved the way for the first international workshop on Archaeobacteria at München-Martinsried, June 27–July 1, 1981. W. Zillig, O. Kandler, and K. Stetter were involved in setting up the workshop, which was supported by the Stiftung Volkswagenwerk and the Max-Planck-Gesellschaft. The workshop was devoted to all areas of Archaeobacterial research, with emphasis on molecular and biochemical research as well as geochemical, paleontological, and taxonomic areas. Over 50 workers attended, and it was the first time that many workers in the field had a chance to meet personally. Participants were enthusiastic about the success of the workshop. It was clear that the Schwerpunkt was not only focusing the efforts of German microbiologists on Archaeobacteria but was having an international impact as well. It was also clear that German microbiologists had assumed a leadership role in the study of the Archaeobacteria.

The proceedings of the 1st International Workshop were published in May 1982 (Kandler, 1982). The 17 articles covering cell walls, the ribosome, translation apparatus, transcription, lipids, membranes, coenzymes, CO₂ fixation, anaerobic reduction of molybdenum, phylogeny, new species, and 5S ribosomal RNA well documented the beautiful flowering of the Archaeobacterial concept that had occurred in just five years! To celebrate the breakthrough of the Archaeobacterial concept after the workshop, Kandler and his wife Trudy took Woese and Wolfe for a hike in the Bavarian Alps to the top of “Hohe Hiss” 1850 m, 80 km south of Munich. Woese and especially Wolfe were not in top physical shape, but with some huffing and puffing, they reached the top via a well-graded path. The photograph (Fig. 1) was taken by Trudy Kandler at the summit. After we returned to the car, the Kandlers showed us some beautiful Bavarian churches, and then, because it was a hot afternoon, we stopped at an open-air beer garden for

a glass of beer under a large linden tree. The beer was delivered to us in large graceful glasses, and after “Prost” (to your health in English), we each had a sip of the cold beer. Otto Kandler seemed to have consumed about a third of the beer in his glass, when he pronounced, “Ah, the first sip is the best!” I have always remembered the volume of a German “sip” on a hot afternoon.

In 1985, owing to the fast-growing field of Archaeobacterial research, international symposia were again organized in Germany. The second International Workshop on Biology and Biochemistry of Archaeobacteria was organized by O. Kandler and K. O. Stetter and sponsored by the Deutsche Forschungsgesellschaft. A workshop on Molecular Genetics of Archaeobacteria was organized by W. Zillig and A. Böck and sponsored by the European Molecular Biology Organization (EMBO) and the Max-Planck-Gesellschaft (München). These workshops were held back-to-back June 23–July 1, 1985, in München. Proceedings of the workshops were published in a volume entitled *Archaeobacteria '85* (Kandler and Zillig, 1986). The book contains 65 reprints of papers and 38 extended poster abstracts and thoroughly documents the astounding progress made in all aspects of the Archaeobacteria in four years (1981–1985). Again, German microbiologists took a leadership role and were ahead of the international community of microbiologists in fully accepting evidence for the three domains of life as indisputable; in contrast, misunderstandings, doubts, and hesitation prevented many microbiologists in other countries from embracing the Archaeobacterial concept. It would be perhaps another 10 years before the concept was fully accepted.

It should be reemphasized that the road was difficult and experimentally demanding, especially in the early years, when Carl Woese’s laboratory alone generated the primary data. To obtain the radioactive nucleotides for 2-D fractionation, the microbial cells had to be grown in media from which phosphate had been removed and to which high levels of ³²P-phosphate were added. The trick was to get cells to take up enough radioactive phosphate before they were killed by radiation. The procedure worked well for organisms with a short generation time but was less suitable for slow-growing microbes. The results of the T₁ endonuclease digestion and subsequent fractionation procedures to identify the sequence of each oligonucleotide, i.e., 5-mers to 18-mers, provided data for only about 25% of the 16S rRNA. Yet the whole system for obtaining the similarity coefficient (S_{AB}) for each organism to construct dendrograms of relationship among organisms was developed by Woese within these limitations. The S_{AB} was the method of choice until cloning and sequencing of the 16S rRNA

Fig. 1. (left to right) Carl Woese, Ralph Wolfe, and Otto Kandler celebrate the success of the 1st international workshop on Archaeobacteria in the Bavarian Alps, July 1, 1981.

genes became available. The first to appear was the 16S rRNA gene from *Escherichia coli* (Brosius et al., 1978), and the first archaeal 16S rRNA sequence appeared in 1983 (Gupta et al., 1983). There was a long lag before the complete 16S rRNA sequences became useful, because for comparative studies, a significant number of sequences needed to be determined. Thus, the method of choice now is to clone rDNA from an organism and obtain the complete sequence of the gene encoding 16S rRNA. The increasing number of complete genome sequences of organisms has made analysis relatively simple compared to the initial procedures used by Woese to define the tree of life.

The second edition of *The Prokaryotes* (four volumes published in 1992) recognized the almost unbelievable impact that the work of Carl Woese had in defining the Archaea as well as a 16S rRNA phylogenetic basis for the microbial world. In the 1990s, microbiology textbooks in the United States began to present phylogeny based on 16S rRNA. In 1997, twenty years after the discovery, the textbook *Brock, Biology of Microorganisms* (Madigan et al., 1977) completely endorsed the Archaea and the universal phylogenetic tree based on 16S rRNA. However, the vast inertia invested in the morphological approach to taxonomy and phylogeny, since the time of Linnaeus and later Darwin by the biological community, makes changing the course of such a huge ship very difficult. This is illustrated dramatically in textbooks of general biology from the 1990s that include perhaps a paragraph or so on the Archaeobacteria with very little or nothing on the use of monomer sequences of rRNA to reveal a molecular tree of life. This approach trickles down from college textbooks to high school textbooks, perpetuating the teaching of biology based on morphology. However, in the United States, the 6th edition of the general text *Biology* by Raven and Johnson (2002) refers to taxonomy and phylogeny based on morphology as the “traditional approach” and then proceeds with a well-presented three-page treatment of the domains of life: Eubacteria, Archaea, and Eukarya. So, all is not lost, just delayed. Remember the quote from Max Planck!

Acknowledgments. I thank Otto Kandler and Gary Olsen for kindly providing factual information.

Thermoproteales

HARALD HUBER, ROBERT HUBER AND KARL O. STETTER

Introduction

The order Thermoproteales (Zillig et al., 1981) is one of the three orders of the archaeal phylum Crenarchaeota (Woese et al., 1990). This branch is further represented by the orders Sulfolobales (Stetter, 1989) and Desulfurococcales (Huber and Stetter, 2001b). Members of the Thermoproteales are rod-shaped extreme thermophiles or hyperthermophiles, which grow either as anaerobes or facultative anaerobes. Under autotrophic conditions, they gain energy by oxidation of hydrogen, using sulfur, thiosulfate, sulfite, oxygen, selenate, and arsenate as electron acceptors. Alternatively, they grow by several types of respiration, using sulfur, oxygen, nitrate, nitrite, arsenate, ferric iron, selenate, selenite, L-cystine, and oxidized glutathione as electron acceptors, or by fermentation of organic substrates. Following the classification listed in the new edition of *Bergey's Manual of Systematic Bacteriology* (Huber and Stetter, 2001a), the order Thermoproteales comprises two validly published families, the Thermoproteaceae (Zillig and Stetter, 1982a) and the Thermofilaceae (Burggraf et al., 1997). The members of these two families can be quite easily distinguished by their morphology: The Thermoproteaceae are rods of at least 0.4 μm in diameter, and the Thermofilaceae are very thin rods of only 0.15–0.35 μm .

The term “sulfur-dependent” archaeobacteria (now Archaea) was used formerly to designate the branch which is now the phylum Crenarchaeota. However, several members of the Thermoproteales (and the Desulfurococcales) can replace sulfur by various inorganic or organic compounds for energy formation and are unable to metabolize sulfur or are even inhibited in the presence of sulfur. Therefore, the designation “sulfur-dependent” Archaea (“Archaeobacteria”) should no longer be used.

In the former editions of *Bergey's Manual of Systematic Bacteriology* (Zillig, 1989) and *The Prokaryotes* (Huber and Stetter, 1992), the Thermoproteales represented, together with the order Sulfolobales, one of the two main lineages

of the phylum Crenarchaeota. The order had been comprised of two families (the Thermoproteaceae [Zillig et al., 1981] and the Desulfurococcales [Zillig et al., 1982b]), and the genera *Pyrodictium* (Stetter, 1982; Stetter et al., 1983), *Thermodiscus* (Stetter and Zillig, 1985; Stetter, 2001), and *Staphylothermus* (Fiala et al., 1986) had been tentatively placed within the Thermoproteales on the basis of their physiological properties (Huber and Stetter, 1992). Meanwhile, mainly based on 16S rRNA sequence comparisons, these genera are placed either within the Pyrodictiaceae (*Pyrodictium*) or Desulfurococcales (*Thermodiscus* and *Staphylothermus*) within the novel order Desulfurococcales (Huber and Stetter, 2001b).

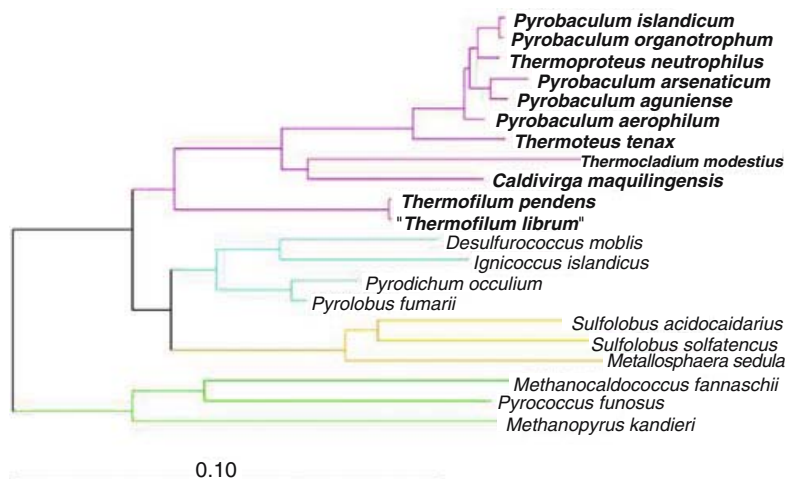

Phylogeny

Based on 16S rDNA sequence data, the order Thermoproteales is a group of the crenarchaeotal branch of the Archaea (Woese et al., 1990). It forms a separate cluster and is distinct from the already mentioned Sulfolobales and Desulfurococcales (Fig. 1). The representatives of the Thermoproteales exhibit phylogenetic similarities between 0.87 and 0.99 to members within the order and 0.77–0.89 (distance matrix values without correction) to all other species of the Crenarchaeota. These values indicate that the order is clearly defined by 16S rDNA gene sequence comparisons and also the two described families are obvious from these results (Fig. 1). Problems arise with members of the genera *Thermoproteus* and *Pyrobaculum*, since they do not form separate clusters in the phylogenetic trees. However, since the two genera are well defined by physiological properties, the present taxonomy is suitable for reidentification of the different species.

Taxonomy

The order Thermoproteales (including the family Thermoproteaceae) was first defined by Zillig and Stetter in 1982 (effective publication: Zillig

Fig. 1. Phylogenetic tree based on 16S rRNA sequences. The tree was calculated using the maximum parsimony program, which is included in the ARB package (Ludwig and Strunk, 2001). Scale bar: 10 estimated exchanges within 100 nucleotides. Red lines = Thermoproteales; blue lines = Desulfurococcales; yellow lines = Sulfolobales; and green lines = Euryarchaeota.

et al., 1981). The description of both taxa was emended by Burggraf et al. (1997). Today, the Thermoproteales are comprised of two families: the Thermoproteaceae containing four validly published genera and the Thermofilaceae containing a single genus (Huber and Stetter, 2001a).

The genus *Thermoproteus* (Zillig et al., 1981), the type genus of the family Thermoproteaceae and the order Thermoproteales, harbors two validly described species: *T. tenax* (Zillig and Stetter, 1982a) and *T. neutrophilus* (Zillig, 1989; Table 1). The type strain for *T. tenax* is strain Kral^T (ATCC 35583^T [American Type Culture Collection, Rockville, MD, United States]) and DSM 2078^T [Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH, Braunschweig, Germany]) and for *T. neutrophilus* strain V24Sta^T (DSM 2338^T and JCM 9278^T [Japan Collection of Microorganisms, Wako, Japan]). Furthermore, *T. uzoniensis* was published by Bonch-Osmolovskaya et al. (1990) and validated recently (deposited strain: Z-605^T, DSM 5263^T; Bonch-Osmolovskaya et al., 2001). The three species are characterized by optimal growth temperatures between 85 and 90°C, an anaerobic mode of life, and the capability of sulfur respiration with complex organic substrates. They can be distinguished by their pH optima and the possibility of being a host for four different rod-shaped viruses.

In contrast to *Thermoproteus*, members of the genus *Pyrobaculum* (Huber et al., 1987; Huber and Stetter, 2001c) are characterized by temperature optima between 90 and 100°C and anaerobic or facultatively anaerobic growth. They can respire sulfur, thiosulfate, oxygen, nitrate, nitrite, ferric iron, selenate, selenite, arsenate, L-cystine or oxidized glutathione. At present, five species are described (Table 1): *P. islandicum* (type strain GEO3^T, DSM 4184^T; Huber et al., 1987),

P. organotrophum (type strain H10^T, DSM 4185^T; Huber et al., 1987), *P. aerophilum* (type strain IM2^T, DSM 7523^T; Völkl et al., 1993), *P. arsenaticum* (type strain PZ6^T, DSM 13514^T and ATCC 700994^T; Huber et al., 2000b), and *P. oguniense* (type strain TE7^T, DSM 13380^T and JCM 10595^T; Sako et al., 2001; Table 1). *Pyrobaculum islandicum*, *P. organotrophum*, and *P. arsenaticum* are obligate anaerobes, while the two other species are facultative anaerobes, which can in addition use oxygen as an electron acceptor. *Pyrobaculum arsenaticum* is characterized by the ability to grow on arsenate, which serves as electron acceptor forming arsenite as metabolic end product. Furthermore, its genomic DNA has a significantly higher G+C content than that of the other members of the genus (58.3 mol%). *Pyrobaculum oguniense* exhibits the lowest temperature optimum of all *Pyrobaculum* species (between 90 and 94°C) and is the only species that does not grow at 100°C. In DNA-DNA hybridization experiments, *P. islandicum* and *P. organotrophum* show a similarity of 65%, indicating that they are closely related to each other, although they can be clearly distinguished by physiological properties, such as metabolic pathways. No significant DNA similarity has been obtained between the other *Pyrobaculum* species including members of the genus *Thermoproteus* (Sako et al., 2001). However, 16S rDNA-based phylogenetic studies revealed that *Thermoproteus neutrophilus* clusters with the *Pyrobaculum* species (Fig. 1). The phylogenetic similarities of the 16S rDNA sequences of the organisms within the cluster are quite high (at least 98.5%).

The genera *Caldivirga* (Itoh et al., 1999) and *Thermocladium* (Itoh et al., 1998b) are both represented by a single species. *Caldivirga maquilingensis* (type strain IC-167^T; JCM 10307^T and MCC-UPLB 1200^T [Microbial Culture Collection of the Museum of Natural History,

Abbreviations: DSM, Deutsche Sammlung von Mikroorganismen; ^T, type strain; n.d., not determined; and JCM, Japan Collection of Microorganisms.

University of the Philippines, Los Banos, the Philippines]) grows heterotrophically under anaerobic or microaerobic conditions. Optimal growth is obtained at weakly acidic pH (3.7–4.2) at 85°C. By 16S rDNA sequence comparisons, the closest relative of *Caldivirga maquilingsensis* is *Thermocladium modestius*, although it clearly represents a different genus. *Thermocladium modestius* (type strain IC-125^T; JCM 10088^T) grows optimally at 75°C, under anaerobic or microaerobic conditions. It is an obligate heterotroph using sulfur, thiosulfate or L-cystine as electron acceptor. Furthermore, the G+C content of the genomic DNA is 52 mol% and therefore significantly different from *Caldivirga maquilingsensis* (43 mol%).

The Thermofilaceae represent the second family within the Thermoproteales, which consists so far of only one genus, *Thermofilum* (Zillig et al., 1983). The characteristic feature of the *Thermofilum* strains is rod-shaped cells with diameter of only 0.15–0.35 µm and length of 1–>100 µm. The organisms are obligate anaerobes which grow by sulfur respiration with complex organic substrates. They are hyperthermophilic with temperature optima between 85 and 90°C. So far, only one species is validly published: *Thermofilum pendens* (type strain Hrk5^T; DSM 2475^T and ATCC 35544^T). Furthermore, “*Thermofilum librum*” was mentioned in several publications, but is so far not validly published and is not listed in the last edition of *Bergey's Manual of Systematic Bacteriology* (Zillig and Reysenbach, 2001).

Habitat

Members of the Thermoproteales have been found exclusively in biotopes of volcanic activity with temperatures up to 100°C and even higher. Representatives of the genera *Thermoproteus*, *Pyrobaculum* and *Thermofilum* have been isolated from springs, water holes, mud holes, and soils of continental solfataric fields with low salinity and acidic to neutral pH values (1.7–7) and found in many places worldwide, including Pisciarelli Solfatara (Italy), Ribeira Quente (the Azores), the Krafla area (Iceland), Yellowstone National Park (United States), Uzon Caldera (Kamchatka), Indonesia, and New Zealand. *Caldivirga* has been obtained from an acidic hot spring in the Philippines and *Thermocladium* from several solfataric areas in Hokkaido, Akita, and Fukushima, Japan. *Pyrobaculum islandicum* was isolated from an outflow of superheated water of an overpressure valve at the Krafla geothermal power plant (Iceland). As an exception, *Pyrobaculum aerophilum* is the only species obtained from a marine hydrothermal system, located at the Maronti Beach, Ischia Island, Italy.

Isolation

Enrichment

Thermoproteus species can be enriched in anaerobic low-salt medium (Allen, 1959), supplemented with elemental sulfur, with a gas phase of H₂/CO₂ (80:20, v/v) at incubation temperatures around 85°C. Alternatively, peptides, amino acids, glycogen, starch, or acetate can serve as carbon sources during sulfur respiration. Members of the genus *Pyrobaculum* can be selectively enriched using incubation temperatures of around 100°C. With the exception of *P. aerophilum* (which needs a half strength seawater medium for enrichment and cultivation), all *Pyrobaculum* species grow in low salt media (pH ~6), which are supplemented with complex organic substrates, like peptides or yeast extract. *Pyrobaculum arsenaticum* can be selectively enriched using arsenate as sole electron acceptor, while *P. islandicum* can be grown in a medium without organic components. For *P. aerophilum* and *P. oguniense*, enrichment under microaerobic conditions is successful. A highly selective enrichment method for strains of the extremely thin *Thermofilum* cells involves passage through a 0.2 µm sterile filter and incubation of the filtrate at 85°C with yeast extract or cell extract of *Thermoproteus tenax*, and elemental sulfur, with a gas phase of H₂/CO₂ (80:20, v/v).

Isolation Procedures

Anaerobic or microaerobic culture media are inoculated with 0.5–1 ml of environmental samples. The culture attempts are examined for growth by phase microscopy over a period of up to four weeks. The isolates are obtained from the enrichment cultures by serial dilutions (three times) or by plating. The plates can be solidified by 20% starch or by 0.6–0.8% Gelrite, and colonies are visible within 1–2 weeks.

Selected single cell isolation using the “optical tweezers trap”:

For a safe, efficient and fast isolation of organisms from mixed cultures, including the Thermoproteales, a novel, plating-independent isolation procedure was developed (Huber et al., 1995). The method is based on separation of a single cell from enrichment cultures by the use of a laser microscope and subsequent growth of this cell. The “optical tweezers trap” (also called the “laser trap”) consists of a computer-controlled inverted microscope. This microscope is equipped with a continuously operating neodymium-doped yttrium aluminum garnet laser (Nd:YAG laser) with an emission wavelength of 1064 nm, which is near infrared, and a maximum output power of 2.5 Watts. By the use

of a high-numerical-aperture oil immersion objective (magnification 100X), the laser can be focused to a spot size of less than 1 μm in diameter. The strong intensity of the laser light makes optical trapping and manipulation in three dimensions of single μm -size cells possible (Ashkin and Dziedzic, 1987a; Ashkin et al., 1987b). The micromanipulation of the cells is performed by keeping the laser beam at a fixed position and moving the motor-driven mechanical stage.

The cell separation unit consists of a rectangular micro-slide as an observation and separation chamber (inside dimension: $0.1 \times 1 \text{ mm}^2$; length: 10 cm), which is connected by a tube to the needle of a 1-ml syringe (Huber et al., 1995; Huber, 1999; Fig. 2a). A cutting line separates the micro-slide into two compartments (Fig. 2a). After sterilization of the cell separation unit, about 90% of the micro-slide is filled with sterile medium. The mixed culture is then filled into the remaining volume of the micro-slide. Under 1000-fold magnification, a single cell is selected and is optically trapped in the laser beam by activation of the laser (Fig. 2a). Within 3–10 min, this cell can be separated at least 6 cm from the mixed culture into the sterile compartment by moving the microscopic stage (Huber, 1999; Fig. 2b). The micro-slide is gently broken at the cutting line, and the single cell is flushed into sterile medium ("selected cell cultivation technique"). Depending on the strain, 20–100% of the separated cells from logarithmically growing enrichment cultures generate pure cultures within only 1–5 days. In addition, the combination of the "selected cell cultivation technique" and the use of the membrane potential-sensitive probe 1,3-dibutylbarbituric acid trimethine oxonol (DiBAC₄(3)) can enhance the isolation of novel organisms either from enrichment cultures or directly from natural samples (Beck and Huber, 1997).

Fig. 2. A schematic drawing showing the isolation of a single cell from an enrichment culture by use of a laser microscope. a) A single cell is optically trapped within the focus of the laser beam. b) The single cell is separated from the mixed culture into the sterile compartment. 1: Microslide; 2: tube; 3: needle; 4: syringe; 5: cutting line; 6: mixed culture; and 7: objective.

Identification

Members of the Thermoproteales are rod-shaped cells about 0.15–0.7 μm in diameter and 1–100 μm in length (Table 1). They do not divide by septa formation, but snapping division has been observed (Horn et al., 1999). Spores are not formed. The cell envelope S-layer is composed of protein or glycoprotein subunits in hexagonal dense packing; no muramic acid is present. The DNA-dependent RNA polymerase is resistant to rifampicin and streptolydigin. Lipids contain glycerol ethers of polyisoprenoid C₄₀ alcohols and a lesser amount of C₂₀ alcohols (De Rosa et al., 1986; Langworthy and Pond, 1986). The G+C contents of genomic DNA range from 43 to 58 mol% (Table 1). The Thermoproteales are anaerobic to facultatively anaerobic organisms with optimal growth temperatures between 75 and 100°C and a pH range from 2 to 8 with an optimum around 5 to 6.5.

Cells of *Thermoproteus* are straight, nonmotile rods, with pili attached laterally and/or terminally. Branching forms are occasionally found. When cells are observed at room temperature under aerobic conditions, spherical bodies ("golf clubs") can be observed, mostly at the terminal end of the rods (Zillig et al., 1981; Fig. 3a, b). In

Fig. 3. Electron micrographs of cells of *Thermoproteus tenax*: a) Pt-shadowed; b) thin section; and c) freeze-etched. Bar: 1 μm for a) and c) and 0.5 μm for b).

contrast, they cannot be detected under anaerobic conditions at growth temperature, using a phase contrast microscope with a heatable stage (Horn et al., 1999). The cell envelopes of *Thermoproteus tenax* and *Thermoproteus neutrophilus* exhibit proteins arranged in p6-symmetry and a lattice constant of approx. 30 nm (Messner et al., 1986). Analysis of the lattice orientation, together with the number and distribution of lattice faults on intact cells, provides a strong indication that the S-layers of both organisms have a shape determining function (Messner et al., 1986). The layer of *Thermoproteus tenax* can be seen as a helical structure consisting of a right-handed, two-stranded helix, with the individual chains running parallel (Wildhaber and Baumeister, 1987; Fig. 3c). For *T. tenax*, four different temperate viruses of the *Lipothrixviridae* and *Bacilloviridae* have been identified (Zillig et al., 1996). While the *Lipothrixviridae* are flexible filaments, the *Bacilloviridae* are stiff rods. New types of menaquinones have been described within the genus *Thermoproteus* (Thurl et al., 1985). The DNA-dependent RNA polymerase shows the BAC-type and is resistant to rifampicin and streptolydigin. Furthermore, two D-glycerate-3-phosphate dehydrogenases have been characterized (Hensel et al., 1987).

Cells of *Pyrobaculum* are cylinder-shaped, rigid rods with nearly rectangular ends (Fig. 4). About 1–10% of the rods form terminal spherical bodies at the end of the exponential growth phase, similar to the “golf clubs” of *Thermoproteus* (Zillig et al., 1981). In the stationary phase, the terminal spheres of *Pyrobaculum aerophilum* tend to enlarge, and several rods convert completely into spheres during further incubation. Cultures of *P. aerophilum* contain about 50% coccoid cells at high nitrate concentrations or pH values above 8.0. *Pyrobaculum* species are flagellated and show motility, which can be strongly enhanced by heating a microscopic slide to about 90°C. The cell envelope of *Pyrobaculum organotrophum* is composed of two distinct hexagonally arrayed crystalline protein layers. Fibrils appear to be sandwiched between the two layers. The outer layer has a p6 symmetry and a

Fig. 4. Electron micrograph of a Pt-shadowed *Pyrobaculum aerophilum* cell with monopolar flagellation. Bar: 1 μ m.

lattice spacing of 20.6 nm (Phipps et al., 1991). In contrast, the cell wall of *P. aerophilum* and *Pyrobaculum islandicum* consists of one S-layer with a p6 symmetry and is connected via a spacer to the cytoplasmic membrane (Phipps et al., 1990; Völkl et al., 1993). An additional surface coat of fibrillar material covers the S-layer (Phipps et al., 1990; Rieger et al., 1997). A novel type of cell-to-cell connection in the form of thin tubes approximately 15–20 nm in diameter was identified in *P. aerophilum* (Rieger et al., 1997). The complex lipids of the *Pyrobaculum* species consist mainly of phosphoglycolipids of types I and II, while aminophospholipids are absent (Trincone et al., 1992; Völkl et al., 1993). The core lipids are mainly composed of acyclic and cyclic glycerol diphytanil glycerol tetraethers with one to four pentacyclic rings. In addition, traces of glycerol diphytanil glycerol diethers are present (Trincone et al., 1992; Völkl et al., 1993). Fully saturated menaquinones have been identified in *P. islandicum* and *P. organotrophum* (Tindall, 1989; Tindall et al., 1991). In *P. islandicum*, a highly thermostable glutamate dehydrogenase was identified, which requires NAD⁺ as a coenzyme for L-glutamate deamination (Kujo and Ohshima, 1998). Furthermore, a dissimilatory siroheme-sulfite-reductase-type protein was detected, which has an $\alpha_2\beta_2$ structure and contains high-spin siroheme, non-heme iron and acid-labile sulfide (Molitor et al., 1998). In addition, *P. islandicum* contains two new tRNA nucleosides, 3-hydroxy-*N*-[[(9- β -D-ribofuranosyl-9*H*-purine-6-yl)amino]carbonyl]norvaline and 3-hydroxy-*N*-[[(9- β -D-ribofuranosyl-9*H*-2-methyl-thiopurine-6-yl)amino]carbonyl]norvaline (Reddy et al., 1992). In *P. aerophilum*, a subtilisin-type protease (“aerolysin”) with activity between 80–130°C was identified, and cytochrome oxidases with novel prenylated hemes as cofactors were present (Lübben and Morand, 1994; Völkl et al., 1994). *Pyrobaculum islandicum* and *P. organotrophum* are resistant to streptomycin, phosphomycin, chloramphenicol, penicillin G and vancomycin (100 μ g/ml). In the presence of rifampicin (100 μ g/ml), a temporary growth inhibition occurs.

Cells of *Thermocladium* (Itoh et al., 1998b) are straight or slightly curved rods (Table 1), which are nonmotile and multiply by branching and budding. In addition, bent cells, branched cells forming T-shapes or Y-shapes, and extensively branched cells occur. At least five tetraether core lipids containing cyclopentane rings in the isoprenyl chains have been identified. The organism is insensitive to chloramphenicol, kanamycin and oleandomycin, but sensitive to rifampicin.

Cells of *Caldivirga* (Itoh et al., 1999) are straight or slightly curved rods, occasionally bent

Fig. 5. Electron micrograph of a single Pt-shadowed cell of *Thermofilum pendens*. Bar: 1 μm .

or branched. They are highly variable in length (usually 3–20 μm), but occasionally reach up to 50 μm (Table 1). Furthermore, globular bodies are observed, located at the cell poles, sometimes also laterally. Pili are attached to the cells, and no motility is observed. *Caldivirga* possesses at least five cyclized glycerol-bisphythanyl-glycerol tetraethers. The organism is insensitive to chloramphenicol, kanamycin, streptomycin and oleandomycin, but sensitive to rifampicin, erythromycin and novobiocin.

Cells of *Thermofilum* (Zillig et al., 1983) are extremely thin rods (Fig. 5) and can be easily overlooked in the microscope. The length varies between 1 and 100 μm , but the diameter of the cells is only 0.17–0.35 μm . Cells are only rarely branched or with sharp bends. Tetraether lipids in combination with very low amounts of 2,3-di-*O*-phythanyl-*sn*-glycerol are typical for this genus.

Cultivation

Media for Cultivation

Basal Culture Medium for *Thermoproteus*, *Thermofilum*, *Pyrobaculum islandicum*, *Pyrobaculum organotrophum* and *Pyrobaculum oguniense*

(Modified Medium of Allen, 1959)

$(\text{NH}_4)_2\text{SO}_4$	1.30 g
KH_2PO_4	0.28 g
$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	0.25 g
$\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$	0.07 g
$\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$	0.02 g
$\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$ (10 mg/ml)	180 μl
$\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$ (10 mg/ml)	450 μl
$\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ (10 mg/ml)	22 μl
$\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ (10 mg/ml)	5 μl
$\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$ (10 mg/ml)	3 μl
$\text{VO}_2\text{SO}_4 \cdot 5\text{H}_2\text{O}$ (10 mg/ml)	3 μl
$\text{CoSO}_4 \cdot 7\text{H}_2\text{O}$ (10 mg/ml)	1 μl
Yeast extract (Bacto Difco)	0.20 g
Resazurin	1.0 mg
Elemental sulfur	2.0 g

Dissolve components in and dilute up to 1 liter with distilled water.

For *P. islandicum* and *P. organotrophum*, add 0.05% peptone (Bacto Difco), adjust pH to 6.0, and grow in gas phase of N_2 (300 kPa). Both

species can also be cultivated in 1/20 MG-CB-medium (see below).

For *P. oguniense*, replace sulfur by 0.1% $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$, adjust pH to 6.5–7.5, and grow aerobically in gas phase of air or anaerobically in N_2 (200 kPa).

For *Thermofilum*, add 20 ml of 10% extract (see below) of *Thermoproteus tenax* or *Methanothermus fervidus* per liter of medium, adjust pH to 6.5, and grow in gas phase of N_2/CO_2 (300 kPa).

For *Thermoproteus tenax*, adjust pH to 5.5, and grow in gas phase of N_2/CO_2 (300 kPa).

For *T. neutrophilus*, adjust pH to 6.5, and grow in a gas phase of H_2/CO_2 (300 kPa).

Culture Medium for *Thermoproteus uzoniensis*

(Bonch-Osmolovskaya et al., 1990)

NH_4Cl	0.33 g
KCl	0.33 g
$\text{MgCl}_2 \cdot 2\text{H}_2\text{O}$	0.33 g
$\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$	0.33 g
KH_2PO_4	0.33 g
Peptone	2.5 g
Yeast extract	0.1 g
Elemental sulfur	10.0 g
Trace element solution (see below)	1.0 ml
Resazurin	1.5 mg

Dissolve components in and dilute up to 1 liter with distilled water. Adjust pH to 6.5 and grow in gas phase of N_2/CO_2 (300 kPa).

Trace Element Solution

(Pfennig and Lippert, 1966)

Nitritotriacetic acid	500 mg
$\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$	200 mg
H_3BO_3	30 mg
$\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$	20 mg
$\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$	10 mg
$\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$	3 mg
$\text{Na}_2\text{MoO}_4 \cdot 2\text{H}_2\text{O}$	3 mg
$\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$	2 mg
$\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$	1 mg

Dissolve components in and dilute up to 1 liter with distilled water. Adjust pH to 6.5 with KOH.

Culture Medium for *Pyrobaculum aerophilum*

(BS medium; Völkl et al., 1993)

NaCl	5.89 g
$\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$	2.82 g
NaHCO_3	2.20 g
Na_2SO_4	0.41 g
$\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$	0.39 g
NH_4Cl	0.25 g
KCl	0.15 g
$(\text{NH}_4)_2\text{Fe}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ (0.2%)	1.0 ml

$MnSO_4 \cdot H_2O$	5.0 g
NaCl	10.0 g
$Ni(NH_4)_2(SO_4)_2 \cdot 6H_2O$	2.8 g
$CoSO_4 \cdot 7H_2O$	1.8 g
$ZnSO_4$	1.8 g
$FeSO_4 \cdot 7H_2O$	1.0 g
$CaCl_2 \cdot 2H_2O$	1.0 g
$KAl(SO_4)_2 \cdot 12H_2O$	0.18 g
$CuSO_4 \cdot 5H_2O$	0.1 g
H_3BO_3	0.1 g
$Na_2MoO_4 \cdot 2H_2O$	0.1 g
$Na_2WO_4 \cdot 2H_2O$	0.1 g
Na_2SeO_4	0.1 g

Dissolve components in and dilute up to 1 liter with distilled water. Adjust pH to 6.5 with KOH.

Trace Vitamin Solution

(Balch et al., 1979)

Vitamin B ₆ (pyridoxine) hydrochloride	10 mg
Vitamin B ₁ (thiamine) hydrochloride	5 mg
Vitamin B ₂ (riboflavin)	5 mg
Nicotinic acid (niacin)	5 mg
Pantothenic acid (DL Ca-pantothenate)	5 mg
PABA (<i>p</i> -aminobenzoic acid)	5 mg
Lipoic (thioctic) acid	5 mg
Biotin	2 mg
Folic acid	2 mg
B12 (crystalline)	0.1 mg

Dissolve components in and dilute up to 1 liter with distilled water.

Culture Medium for *Pyrobaculum arsenaticum*, *Pyrobaculum islandicum* and *Pyrobaculum organotrophum* (1/20 MG-CB-medium)

$MgCl_2 \cdot 6H_2O$	1215 mg
NaCl	900 mg
$NaHCO_3$	500 mg
$CaCO_3$	50 mg

KCl	17 mg
NH_4Cl	12 mg
$CaCl_2 \cdot 2H_2O$	7 mg
$K_2HPO_4 \cdot 3H_2O$	7 mg
$(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$	0.1 mg
Trace vitamin solution (see above)	10 ml
Trace mineral solution (see below)	10 ml
Resazurin	5 mg

Dissolve components in and dilute up to 1 liter with distilled water. Adjust pH to 6.5–7 with HCl, and grow in gas phase of H_2/CO_2 (300 kPa).

Trace Mineral Solution

(a modification of that described by Balch et al., 1979)

$MgCl_2 \cdot 6H_2O$	2.48 g
$MnCl_2 \cdot 4H_2O$	0.53 g
NaCl	1.0 g
$FeCl_2 \cdot 4H_2O$	0.72 g
$CoCl_2 \cdot 6H_2O$	0.18 g
$CaCl_2 \cdot 2H_2O$	0.1 g
$ZnCl_2$	0.09 g
$CuCl_2 \cdot 2H_2O$	6.8 mg
KCl	3.15 mg
$AlCl_3$	5.6 mg
H_3BO_3	0.01 g
$Na_2MoO_4 \cdot 2H_2O$	0.01 g
$Na_2WO_4 \cdot 2H_2O$	0.01 g
Na_2SeO_4	0.01 g
$NiCl_2 \cdot 6H_2O$	0.14 g

Dissolve components in and dilute up to 1 liter with distilled water. Adjust to pH 1.5 with HCl.

Culture Medium for *Thermocladium* and *Caldivirga*

(TCD medium; Itoh et al., 1998b)

$(NH_4)_2SO_4$	1.30 g
KH_2PO_4	0.28 g
$MgSO_4 \cdot 7H_2O$	0.25 g
$CaCl_2 \cdot 2H_2O$	0.07 g
Combined trace element solution	1.0 ml
Yeast extract	0.5 g
Resazurin	1.0 mg
Sulfur powder	10.0 g

Dissolve components in and dilute up to 1 liter with distilled water. Adjust pH to 4–4.5 and grow in gas phase of H_2/CO_2 or N_2 (100 kPa).

Combined Trace Element Solution

$FeCl_3 \cdot 6H_2O$	20.00 g
$Na_2B_4O_7 \cdot 10H_2O$	4.50 g
$MnCl_2 \cdot 4H_2O$	1.80 g
$ZnSO_4 \cdot 7H_2O$	0.22 g
$CuCl_2 \cdot 2H_2O$	0.05 g
$VO_2SO_4 \cdot 5H_2O$	0.04 g
$Na_2MoO_4 \cdot 2H_2O$	0.03 g
$CoSO_4 \cdot 7H_2O$	0.01 g

Dissolve components in and dilute up to 1 liter with distilled water. Adjust pH to 1.5.

For growth of *Thermocladium modestius*, add 1 ml of archaeal cell-extract solution from *Sulfolobus acidocaldarius*, *Methanosarcina barkeri*, *Halobacterium salinarum* or *Thermoplasma acidophilum*.

For growth of *Caldivirga maquilgensis*, add 10 ml of trace vitamin solution (see above).

Preparation of Cell Extracts

Ten g of cells (wet weight) are suspended in 40 ml of distilled water and disrupted by a French press. The volume of the homogenate is adjusted to 100 ml, the homogenate is centrifuged, and the supernatant is passed through a sterile filter (0.2- μ m pore width) into a sterile serum bottle. After gassing the filtered supernatant with nitrogen, oxygen is reduced by the addition of 1 ml of Na_2S solution (2.5%). The extracts (designated "10% extracts") are stored at 4°C.

Cultivation in Liquid Media

All anaerobic members of the Thermoproteales are cultivated using the anaerobic technique of Balch and Wolfe (1976). For small volumes, the organisms are grown in stoppered and pressurized 28-ml serum tubes (boric silicate glass; Schott, Mainz, Germany) or in 120-ml serum bottles (Bormioli, Italy) made of "type III" glass. One liter of the medium is flushed with nitrogen for 20 min in a stoppered glass bottle. Then, 0.5 g of $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$, dissolved in 1 ml of medium, are added with a syringe and the medium is adjusted to the desired pH with H_2SO_4 or HCl. The medium is dispensed in an anaerobic chamber. The culture vessels are stoppered, and the gas phase is exchanged three times. Finally, the desired gas phase is pressurized.

Cultivation on Plates

Microcolonies (diameter about 0.5 mm) of *Thermoproteus* and *Thermofilum* are obtained on 5% polyacrylamide gels (Zillig et al., 1981) at 85°C in an atmosphere of 100 kPa N_2 plus 20 kPa H_2S and 20 kPa CO_2 in an anaerobic jar. *Pyrobaculum islandicum* can be plated under anaerobic conditions, using a stainless-steel anaerobic jar (Balch et al., 1979) and plates of medium solidified by 20% starch and containing thiosulfate instead of sulfur. After anaerobic incubation for about seven days at 85°C, tiny, greenish-black colonies will be formed. *Pyrobaculum aerophilum* can be cultivated on plates of medium solidified by 0.6% Gelrite, and these plates are incubated in a stainless-steel anaerobic jar at 85°C. (Note: If the medium is of low ionic strength, 0.4% MgSO_4 should be added for a better solidification of the Gelrite). Round grayish-yellow colonies will be visible after about two weeks. High plating efficiencies approaching 100% can be obtained on Gelrite plates at 92°C under aerobic conditions and an incubation time of only four days (Völkl et al., 1993). For *Thermocladium modestius* and *Caldivirga maquilensis*, no plating procedures have been reported.

Preservation

For short-time storage, most Thermoproteales isolates can be stored at 4°C for several months. In contrast, *P. aerophilum* should be transferred once a week, when stored at 4°C. Long-term storage is best achieved in culture media containing 5% dimethyl sulfoxide and in the gas phase over liquid nitrogen (which is around -140°C). No loss of cell viability of *Pyrobaculum*- and *Thermoproteus* relatives was observed after storage of about ten years.

Physiology

Within the Thermoproteales, only extreme thermophiles or hyperthermophiles are known with optimal growth temperatures between 75 and 100°C. With the exception of *Thermocladium modestius*, no Thermoproteales organisms have been observed to grow below 60°C (Table 1). Almost all Thermoproteales grow best at slightly acidic pH values (pH 4–6; Table 1). Since the natural habitats of all Thermoproteales except *Pyrobaculum aerophilum* are terrestrial solfataric fields, optimal growth is obtained in media of low ionic strength (Table 1). All members of the Thermoproteales are able to grow under strictly anaerobic culture conditions. In addition, *Pyrobaculum aerophilum*, *Thermocladium modestius* and *Caldivirga maquilensis* propagate in the presence of low oxygen concentrations (e.g., *Pyrobaculum aerophilum* up to 6% oxygen), while *Pyrobaculum oguniense* can grow under aerobic conditions.

Facultative and obligate heterotrophs are known within the Thermoproteales (Table 1). Under autotrophic conditions, molecular hydrogen is used as the electron donor, and sulfur is reduced to hydrogen sulfide (H_2S). Beside sulfur, *Pyrobaculum arsenaticum* can use arsenate and thiosulfate as alternative electron acceptors. *Pyrobaculum aerophilum* grows autotrophically with hydrogen and thiosulfate, arsenate, nitrate, oxygen or selenate (Völkl et al., 1993; Huber et al., 2000a).

Heterotrophic growth occurs by sulfur respiration using various organic substrates (e.g., glucose, starch, glycogen, fumarate, peptides, and several amino acids [genus *Thermoproteus*]) and gelatin and complex organic substrates (e.g., beef extract, peptone, tryptone, and yeast extract [genera *Thermofilum*, *Caldivirga* and *Thermocladium*]). Besides sulfur, thiosulfate or sulfate (*Caldivirga*) or L-cystine (*Thermocladium*) can serve as an alternative electron acceptor. *Pyrobaculum oguniense* and *Pyrobaculum organotrophum* (both obligate heterotrophs) and

Pyrobaculum islandicum grow anaerobically on peptone, yeast extract, meat extract and cell homogenates of bacteria (e.g., *Thermotoga maritima*) or archaea (e.g., *Staphylothermus marinus*) in the presence of sulfur, L(–)-cystine or oxidized glutathione or on yeast extract combined with hydrogen and ferric iron (Kashefi and Lovley, 2000). DL-Lanthionine, tetrathionate, thiosulfate, sulfite, dimethyl sulfone, fumarate, or sulfate is not used as electron acceptor. No growth occurs on glycogen, starch, maltose, galactose, glucose, casamino acids, formamide, methanol, ethanol, formate, malate, propionate, L(+)lactate or acetate. *Pyrobaculum aerophilum* grows microaerophilically in the presence of complex organic substrates (and propionate and acetate) by nitrate reduction (producing nitrite and traces of nitric oxide [NO]) and by nitrite reduction (forming N₂ and traces of N₂O and NO as final products). Nitrous oxide (N₂O) is not used as an alternative electron acceptor. Growth of *Pyrobaculum aerophilum* and *Pyrobaculum oguniense* was inhibited by elemental sulfur. *Pyrobaculum arsenaticum* grows anaerobically by respiration of arsenate, selenate, thiosulfate or elemental sulfur.

In *Pyrobaculum islandicum*, *Pyrobaculum organotrophum* and *Thermoproteus tenax* the complete oxidation of organic compounds to CO₂ proceeds via the citric acid cycle (Selig and Schönheit, 1994). Furthermore, in *Thermoproteus tenax*, two glyceraldehyde phosphate (GAP)-dehydrogenases have been found, one specific for NAD⁺, the second for NADP⁺. In *Thermoproteus neutrophilus*, a reductive citric acid cycle for carbon assimilation was found (Schäfer et al., 1986). Glycogen was present in *Thermoproteus* (König et al., 1982), while trehalose was absent (Nicolaus et al., 1988).

Thermofilum pendens has unusual growth factors. For growth, the cell debris or a polar lipid fraction of *Thermoproteus tenax* must be added to the medium (Zillig et al., 1983). These fractions can be substituted by a similar fraction obtained from methanogens (Stetter, 1986) but not by a fraction from *Thermoplasma* (Zillig et al., 1983) or by combined fractions from different bacteria (Stetter, 1986).

Genetics

A 713-bp intron, which cyclizes upon excision, was identified in the 16S rRNA gene of *Pyrobaculum aerophilum*. The intron contains an open reading frame whose protein translation shows no statistically significant homology with any known protein sequence (Burggraf et al., 1993). Two introns occur within the single 23S rRNA-

encoding gene of *Pyrobaculum organotrophum*. The RNA products also circulate after excision from the 23S rRNA and are stable in the cell (Dalgaard and Garrett, 1992). Furthermore, an intron was detected in the 16S rRNA genes of *Thermoproteus neutrophilus* and *Thermoproteus* spp. (Itoh et al., 1998a), while two introns were located in this gene in *Caldivirga maquilingensis* (Itoh et al., 1999). However, the taxonomic significance of these introns is still unclear.

The sequencing and annotation of the complete 2.2 Mb genome of *Pyrobaculum aerophilum* by three groups under the leadership of the California Institute of Technology were published very recently (Fitz-Gibbon et al., 2002). This sequence has been deposited in the GenBank database (accession number).

Ecology

Representatives of the Thermoproteales thrive in neutral to slightly acidic biotopes, covering temperatures from 45 up to 104°C. With the exception of *Pyrobaculum aerophilum*, they are typical inhabitants of high-temperature continental solfataric areas. They have been isolated from such biotopes nearly world-wide. They often share these habitats with other thermophilic and hyperthermophilic organisms such as members of the orders Sulfolobales, Desulfurococcales, Thermotogales and Aquificales. Such hot solfataric soils often consist of two dominating different zones. The upper oxidized zone is often rich in ferric iron and therefore colored orange. In a depth between a few centimeters and about 50 cm, depending on the volcanic activity and emission of reducing volcanic gases (e.g., H₂S and H₂) below these oxidized layers, the anaerobic zone (often black-colored due to the presence of ferrous sulfide) begins. The chemical composition of the solfataric fields is highly variable and depends on the site. Often iron, followed in quantity by arsenic and antimony, is found in these habitats (Huber et al., 2000a).

In their ecosystem, the Thermoproteales are important organisms within complex food webs. They can function as primary producers and/or as consumers of organic material. As primary producers, they use oxygen, elemental sulfur, sulfate, thiosulfate, sulfite, and nitrate as electron acceptors for growth and molecular hydrogen as the electron donor in these energy-yielding reactions. Recently, it was shown that heavy metal compounds are also suitable electron acceptors for several members of *Pyrobaculum* that can reduce ferric iron to form magnetite (Stetter, 1999). By coexistence with anaerobic iron oxidiz-

Fig. 6. Organotrophic growth of *Pyrobaculum arsenaticum* at 95°C in the presence of 10 mM arsenate and 0.1% thiosulfate (gas phase 300 kPa $H_2/CO_2 = 80:20$, v/v). a) Yellow-orange precipitate is realgar (As_2S_2) and b) uninoculated control.

ers such as *Ferroglobus placidus*, a hot iron cycle can be postulated, which may have existed already within the ecosystems of early life forms on earth (Stetter, 2000). Also, autotrophic arsenate and/or selenate reduction with hydrogen as the electron donor occurs under anaerobic conditions by *Pyrobaculum arsenaticum* and *Pyrobaculum aerophilum* (Huber et al., 2000b).

The obligate heterotrophs, growing by different types of respiration or fermentation, are consumers of the organic matter. For anaerobic respiration, sulfur, sulfurous compounds and nitrate are used as electron acceptors. *Pyrobaculum arsenaticum* grows heterotrophically in the presence of thiosulfate or arsenate. Interestingly, when both acceptors are supplied simultaneously, a precipitate (identified as realgar [As_2S_2]) is formed during growth and is visible as yellow-orange flocs in the culture medium (Fig. 6). Arsenate-reducing hyperthermophiles occur in high densities in these natural environments. Pisciarelli Solfatara sediment has been found to contain at least 10^7 viable cells of arsenate reducers per gram (Huber et al., 2000a). Considering these results, hyperthermophilic arsenate reducers may be important members in their high-temperature environment and may be a critical part of a possible combined arsenic and sulfur cycle (Huber et al., 2000b).

Biotechnology

A continuously increasing number of heat stable enzymes from hyperthermophiles is being

checked for industrial and research applications. This includes extracellular enzymes (e.g., amylases, lipases, proteases, or xylanases) and intracellular enzymes (e.g., dehydrogenases, oxidoreductases, and DNA polymerases). The enzymes are usually not extracted from their “parental” hyperthermophiles, but are produced from genetically engineered mesophilic production strains. The total genome sequence of *Pyrobaculum aerophilum* is now available, offering the opportunity to use its genes as tools for different biotechnological applications (Fitz-Gibbon et al., 2002).

Acknowledgments. The authors thank R. Rachel for electron microscopy and Brian Hedlund for critically reading the manuscript.

Sulfolobales

HARALD HUBER AND DAVID PRANGISHVILI

Introduction

Within the crenarchaeotal branch of the Archaea (Woese and Fox, 1977; Woese et al., 1990), three orders have been described so far: the Desulfurococcales (Huber and Stetter, 2001b), the Thermoproteales (Zillig et al., 1981), and the Sulfolobales (Stetter, 1989). Members of the Sulfolobales are well-defined and distinguished from the other orders by morphological, physiological and molecular characters. Cells are regular to irregular cocci, which occur usually singly or in pairs and exhibit cell diameters from about 1.0 up to 5 μm . All members of the order are extreme thermophiles to hyperthermophiles with optimal growth temperatures between 65 and 90°C. An important common property is their pH optimum of around pH 2. They grow aerobically, facultatively anaerobically, or anaerobically. Under autotrophic conditions they gain energy by oxidation of elemental sulfur, thiosulfate, sulfidic ores, or molecular hydrogen. Carbon dioxide (CO_2) is used as a carbon source. Alternatively, organotrophic growth occurs by aerobic respiration or anaerobic sulfur respiration or by fermentation of organic substrates. Following the classification listed in the new edition of *Bergey's Manual of Systematic Bacteriology* (Huber and Stetter, 2001c), the order Sulfolobales comprises one family, the Sulfolobaceae (Stetter, 1989), with six genera and around 20 species. Since the last edition of *The Prokaryotes* (Seeger and Stetter, 1992), several representatives have been renamed and one genus no longer exists (“*Desulfurolobus*”; Zillig et al., 1986). In addition, nucleic acid hybridization studies and 16S rRNA sequencing suggest that most Sulfolobales are genetically rather unrelated, even the phenotypically quite similar species included in the genus *Sulfolobus* (Fuchs et al., 1996; Trevisanato et al., 1996). The members of the genera can be distinguished by their genomic DNA G+C content, the ability of growing aerobically and/or anaerobically, and the use of different electron acceptors. However, probably as a consequence of their common, extreme biotope, the members of the Sulfolobales exhibit

high physiological and morphological similarities. Therefore only a few properties can be used to classify and describe the different genera and species. Some problems have occurred since several type strains of *Sulfolobus* species deposited in culture collections (e.g., *S. acidocaldarius* and *S. solfataricus*) proved to be unable to oxidize elemental sulfur, although this capability was used to define *Sulfolobus* spp. in their original descriptions. The reason for this is unknown, but meanwhile closely related strains that exhibit this physiological property have been isolated. Compared to other archaeal groups, members of the Sulfolobales are quite easy to handle and to cultivate, and so a huge number of molecular investigations has been carried out and even genetic systems have been established. Furthermore, complete genome sequences are available for *S. solfataricus* and *S. tokodaii* (the sequence data for *S. acidocaldarius* and several others are not available at the moment).

Phylogeny

On the basis of 16S rRNA sequence comparisons, the order Sulfolobales represents one lineage of the crenarchaeotal branch of the Archaea (Woese et al., 1990; Fuchs et al., 1996; Fig. 1). It forms a separate cluster and is distinct from the two other described orders of the archaeal phylum Crenarchaeota: the Desulfurococcales and the Thermoproteales. The representatives of the Sulfolobales exhibit phylogenetic similarities of 0.85–1.00 to members within the order and 0.88–0.77 to all other species of the Crenarchaeota (Fuchs et al., 1996; H. Huber, unpublished observation). However, the phylogenetic analysis reveals several differences in the present taxonomy of the Sulfolobales. This is especially true for the genus *Sulfolobus*. Four groups can be identified within this genus on the basis of 16S rDNA sequences (Fig. 1). They exhibit phylogenetic distances of 7–15% from each other (H. Huber, unpublished data), indicating that they are at least different genera. The first group is composed of *S. acidocaldarius* and

Fig. 1. Phylogenetic tree based on 16S rRNA sequences. The tree was calculated using the maximum likelihood program, which is included in the ARB package (Ludwig and Strunk, 2001). Scale bar: 10 estimated exchanges within 100 nucleotides. Red lines = Sulfolobales; blue lines = Desulfurococcales; and green lines = Thermoproteales.

the undescribed species “*S. thuringiensis*.” The second group encompasses *S. tokodaii*, *S. yangmingensis* and *Sulfurisphaera ohwakuensis*. These three organisms represent the same genus, *Sulfurisphaera*, and as a consequence, the two “*Sulfolobus*” species should be reclassified as *Sulfurisphaera* species. The third group includes *S. solfataricus*, *S. shibatae*, the recently published *S. tengchongensis*, and the undescribed “*S. islandicus*,” while the fourth phylogenetic group is represented by *S. metallicus*. However, since there are few significant physiological characteristics for the description, the definition of new genera is based nearly exclusively on sequence data. Nevertheless, it can be expected that further reclassification of members of the genus *Sulfolobus* or other members of the Sulfolobales will occur.

Phylogenetic investigations based on analyses of 23S rRNA sequences were carried out by Trevisanato et al. (1996). The resulting phylogeny was consistent with the 16S rRNA tree, although not all members of the Sulfolobales have been included in this study.

Taxonomy

The first member of the order was isolated by Brierley in Yellowstone National Park, Wyoming, United States, and preliminarily described in his thesis (Brierley, 1966). Full description was published in 1973 (Brierley and Brierley, 1973a), one year after the genus *Sulfolobus* was established (Brock et al., 1972).

Another organism, tentatively named “*Caldariella acidophila*,” was isolated from the Solfatara crater, Naples, Italy (DeRosa et al., 1974). Although phenotypically convergent, it was considered to be phylogenetically distinct from *Sulfolobus* (DeRosa et al., 1975). Subsequent

studies revealed that the DNA-dependent RNA polymerases of *Sulfolobus acidocaldarius*, Brierley’s organism, and strains of “*Caldariella*” were very similar. Consequently, both Brierley’s organism and “*Caldariella*” were described as members of the genus *Sulfolobus* and named “*Sulfolobus brierleyi*” and “*S. solfataricus*,” respectively (Zillig et al., 1980).

In 1984, facultatively anaerobic strains of *Sulfolobus*-related organisms capable of both sulfur-oxidation and sulfur-reduction were isolated (Seegerer et al., 1985) and described as *Acidianus infernus* (Seegerer et al., 1986). With regard to the organism’s capacity for facultative reduction/oxidation of sulfur, the genus name *Acidianus* refers to Ianus, an ancient Roman god with two faces looking in opposite directions. Closely related isolates with similar features were independently obtained by Zillig and coworkers (Zillig et al., 1985). Strain Lei10, tentatively named “*Sulfolobus ambivalens*,” was later described as *Desulfurolobus ambivalens* (Zillig et al., 1986) and in 1996 reclassified as *Acidianus ambivalens* (Fuchs et al., 1996). In addition, *Sulfolobus brierleyi* was recognized to be another facultative sulfur-reducer with the same DNA G+C content of about 31 mol%, which is typical for *Acidianus*. This finding led to an emended description of Brierley’s organism as a member of the genus *Acidianus*, *Acidianus brierleyi* comb. nov. (Seegerer et al., 1986).

Then in 1989, the order Sulfolobales and the family Sulfolobaceae were defined by Stetter in the third edition of *Bergey’s Manual of Systematic Bacteriology* (Stetter, 1989). At present, the Sulfolobales are comprised of one family and six validly described genera (Huber and Stetter, 2001c). In addition to the 16 validated species, three (“*S. islandicus*,” “*S. thuringiensis*” and “*S. tengchongensis*”) are tentatively described (Xiang et al., 2003). Furthermore, a huge number of mostly unclassified species has been used in different investigations.

Several members of the Sulfolobales have been reclassified during the last years and even today, the classification is sometimes not in line with the phylogenetic data obtained, e.g., by 16S rRNA based sequence analysis. In addition, problems arise with strains which are unavailable or not deposited in public culture collections. Notably, for the description of newly described species (or genera) to be valid, the type strains have to be deposited in two independent official culture collections, located in two different countries. Therefore, in this article only validly described species will be discussed in detail.

In many biochemical and molecular studies of Sulfolobales, isolates assigned to one of the validly described species with little verification were used. However, at least in some cases, these iso-

lates differ significantly from the type strains, rendering their taxonomic status questionable (see “Biochemistry”).

The following genera and species have been assigned to the order Sulfolobales:

a) Genus *Sulfolobus* (type genus of the family Sulfolobaceae and the order Sulfolobales) includes *S. acidocaldarius* (type species), *S. acidocaldarius* type strain 98-3^T (American Type Culture Collection [ATCC 33909^T], Deutsche Sammlung von Mikroorganismen und Zellkulturen [DSM 639^T]; Brock et al., 1972); *S. metallicus* (type strain Kra23^T, DSM 5389^T; Huber and Stetter, 1991a); *S. shibatae* (type strain B12^T, DSM 6482^T; Grogan et al., 1990); *S. solfataricus* (type strain ATCC 35091^T, DSM 1616^T; Brock et al., 1972; Zillig et al., 1980); *S. tokodaii* (validated, although only deposited in one public culture collection; type strain 7^T, Japan Collection of Microorganisms [JCM 10545^T]; Suzuki et al., 2002); and *S. yangmingensis* (validated, although not deposited in a public culture collection; type strain YM1^T; Jan et al., 1999). b) Genus *Acidianus* includes *A. infernus* (type species), *A. infernus* type strain So-4a^T (DSM 3191^T; Segerer et al., 1986); *A. ambivalens* type strain Lei1^T (DSM 3772^T; Zillig et al., 1986; Fuchs et al., 1996); and *A. brierleyi* type strain DSM 1651^T (Brierley and Brierley, 1973a; Zillig et al., 1980; Segerer et al., 1986). c) Genus *Metallosphaera* includes *M. sedula* (type species), *M. sedula* type strain TH2^T (DSM 5348^T; Huber et al., 1989); *M. hakonensis* type strain HO1-1^T (ATCC 51241^T, DSM 7519^T, IAM 14250^T, JCM 8857^T; Takayanagi et al., 1996; Kurosawa et al., 2003); and *M. prunae* type strain Ron12/II^T (DSM 10039^T; Fuchs et al., 1995). d) Genus *Stygiolobus* includes *St. azoricus* (type species), *St. azoricus* type strain FC6^T (DSM 6296^T; Segerer et al., 1991). e) Genus *Sulfurisphaera* includes *S. ohwakuensis* (type species), *S. ohwakuensis* type strain TA-1^T (Institute of Fermentation, Osaka, Japan [IFO 15161^T]; Kurosawa et al., 1998). f) Genus *Sulfurococcus* includes *S. mirabilis* (type species), *S. mirabilis* type strain INMI AT-59^T (Golovacheva et al., 1987a; Golovacheva et al., 1987b); and *S. yellowstonensis* type strain Str6kar^T (Karavaiko et al., 1994). These last two strains have no deposition numbers and both are preserved at the Institute of Microbiology, Russian Academy of Sciences, Moscow, Russia!

The main characteristics for distinguishing these genera are summarized in Table 1. Members of the genus *Sulfolobus* are obligate aerobes, which can oxidize a variety of sulfur containing compounds. Most strains are facultative heterotrophs. *Acidianus* strains exhibit a facultative anaerobic mode of life. Under aerobic conditions they oxidize sulfur compounds, H₂, and ferrous iron, while they grow anaerobi-

cally by S⁰-H₂ autotrophy, producing H₂S as the metabolic end product. The G+C content of the genomic DNA is around 31%. *Metallosphaera* cells gain energy by oxidation of sulfur compounds, molecular hydrogen and especially sulfidic ores. All strains are able to grow on complex organic substrates. The DNA G+C content is around 45 mol% (the G+C content of *M. hakonensis* was corrected to 46.2 mol%). The major characteristic of *Stygiolobus azoricus* is its obligate chemolithoautotrophic growth under anaerobic conditions by reduction of elemental sulfur with H₂ as electron donor (S⁰-H₂ autotrophy). Hydrogen sulfide (H₂S) is produced as sole metabolic end product. The DNA G+C content of *Stygiolobus azoricus* is 38 mol%. *Sulfurisphaera ohwakuensis* is a facultative anaerobic organotroph, which grows anaerobically on elemental sulfur and on complex substrates. However, aerobic growth on sulfur compounds is not described. The G+C content of the genomic DNA is 33 mol%. *Sulfurococcus* species are characterized by an obligate aerobic growth, which occurs on sulfur compounds and sugars or complex organic compounds. The G+C content of their genomic DNAs is around 45 mol%.

Habitats

Members of the Sulfolobales have been isolated almost exclusively from continental solfataric fields, where they thrive within hot, highly acidic water- and mud-holes. In addition, representatives have been obtained from acidic hot soils (Fliermans and Brock, 1972) and smoldering slag heaps (Fuchs et al., 1995).

Two different niches, defined by redox state and pH, are present within solfataric fields. The first is an upper, oxygen-containing zone of rusty color (indicating the presence of ferric iron), which is highly acidic (pH ≤ 2) owing to biotic and abiotic oxidation processes (Brock, 1978b; Stetter et al., 1986; Huber et al., 2000). In this zone, an iridescent, oily glimmering layer containing high concentrations (up to 10⁸ cells/ml) of irregular, lobed cells typical for Sulfolobales is commonly seen floating on grayish, boiling mud. The second is a deeper zone of around pH 4, which is anaerobic because of the presence of reducing volcanic exhalations (e.g., hydrogen sulfide) and blackish-gray because of the formation of heavy metal sulfides (Stetter et al., 1986; Huber et al., 2000). Whereas growth of the Thermoproteales is restricted to the reduced depth of solfataras, Sulfolobales species exhibit a broader metabolic diversity (see below) and therefore inhabit both zones.

Table 1. Differentiation of the Sulfolobales species.

Species	Temp (°C) (opt. °C)	pH-range (opt.)	Relation to oxygen	Metabolism	Substrates	G+C content (mol %)	References
<i>Sulfolobus acidocaldarius</i>	55–85 (70–75)	1–6 (2–3)	Aerobic	Mixotrophic or heterotrophic	Complex organic compounds; sugars (e.g., glucose, ribose, sucrose, xylose); and oxidation of molecular hydrogen	37	Brock et al., 1972
<i>Sulfolobus metallicus</i>	50–75 (65)	1–4.5 (2–3)	Aerobic	Obligate lithoautotrophic	Oxidation of sulfidic ores (pyrite, sphalerite, and chalcopyrite); and oxidation of elemental sulfur	38	Huber and Stetter, 1991
<i>Sulfolobus shibatae</i>	n.d.–86 (81)	n.d. (3)	Aerobic	Mixotrophic or heterotrophic	Complex organic compounds; sugars (e.g., glucose, ribose, sucrose, xylose, maltose, and starch); oxidation of molecular hydrogen and elemental sulfur	35	Grogan et al., 1990
<i>Sulfolobus solfataricus</i>	50–87 (85)	2–5.5 (3–4.5)	Aerobic	Mixotrophic or heterotrophic	Complex organic compounds; sugars (e.g., glucose, ribose, sucrose, and xylose); and oxidation of molecular hydrogen	35	Zillig et al., 1980
<i>Sulfolobus tokodaii</i>	70–85 (80)	2–5 (2.5–3)	Aerobic	Chemolithotrophic to chemoheterotrophic	Complex organic compounds; amino acids; and oxidation of elemental sulfur	33	Suzuki et al., 2002
<i>Sulfolobus yangmingensis</i>	65–95 (80)	2–6 (4)	Aerobic	Mixotrophic or heterotrophic	Complex organic compounds; sugars (e.g., glucose, ribose, sucrose, xylose, and maltose); and amino acids (all except cysteine); and oxidation of elemental sulfur	42	Jan et al., 1998
<i>Acidianus infernus</i>	65–95 (85–90)	1–5.5 (2)	Facultative anaerobic	Obligate lithoautotrophic	Oxidation of sulfidic ores (pyrite, sphalerite, and chalcopyrite); oxidation of molecular hydrogen and elemental sulfur; and S ⁰ -H ₂ autotrophy	31	Seegerer et al., 1986
<i>Acidianus ambivalens</i>	n.d.–87 (80)	1–3.5 (2.5)	Facultative anaerobic	Obligate lithoautotrophic	Oxidation of elemental sulfur; and S ⁰ -H ₂ autotrophy	33	Zillig et al., 1986
<i>Acidianus brierleyi</i>	45–75 (70)	1–6 (1.5–2)	Facultative anaerobic	Facultative chemolithoautotrophic	Oxidation of sulfidic ores (pyrite, sphalerite, chalcopyrite); oxidation of molecular hydrogen and elemental sulfur, complex; organic compounds; and S ⁰ -H ₂ autotrophy	31	Fuchs et al., 1996 Zillig et al., 1980 Seegerer et al., 1986

<i>Metallosphaera sedula</i>	50–80 (75)	1.0–4.5 (2–3)	Aerobic	Facultative chemolithoautotrophic	Oxidation of sulfidic ores (pyrite, sphalerite, and chalcopyrite); oxidation of molecular hydrogen and elemental sulfur; complex; and organic compounds	45	Huber G. et al., 1989
<i>Metallosphaera hakonensis</i>	50–80 (70)	1–4 (3)	Aerobic	Facultative chemolithoautotrophic	Oxidation of metal sulfides (FeS); oxidation of elemental sulfur; tetrathionate and H ₂ S; complex; and organic compounds	46	Takayanagi et al., 1996 Kurosawa et al., 2003
<i>Metallosphaera prunae</i>	55–80 (75)	1–4.5 (2–3)	Aerobic	Facultative chemolithoautotrophic	Oxidation of sulfidic ores (pyrite, sphalerite, and chalcopyrite); oxidation of molecular hydrogen and elemental sulfur; complex; and organic compounds	46	Fuchs et al., 1995
<i>Stygiolobus azoricus</i>	57–89 (80)	1–5.5 (2.5–3)	Anaerobic	Obligate chemolithoautotrophic	S ⁰ -H ₂ autotrophy	38	Seeger et al., 1991
<i>Sulfurisphaera ohwakuensis</i>	63–92 (84)	1–5 (2)	Facultative anaerobic	Mixotrophic or heterotrophic	Oxidation of complex; organic compounds; reduction of elemental sulfur with H ₂ and complex organic compounds	33	Kurosawa et al., 1998
<i>Sulfurococcus mirabilis</i>	50–86 (70–75)	1–5.8 (2–2.6)	Aerobic	Facultative chemolithoautotrophic	Oxidation of sulfidic ores (pyrite, sphalerite, and chalcopyrite); oxidation of elemental sulfur; complex; organic compounds; and sugars and amino acids	~44	Golovachewa et al., 1987a, b Karavaiko et al., 1995
<i>Sulfurococcus yellowstonensis</i>	40–80 (60)	1–5.5 (2–2.6)	Aerobic	Facultative chemolithoautotrophic	Oxidation of sulfidic ores (pyrite, sphalerite, and chalcopyrite); oxidation of elemental sulfur and ferrous iron; complex; organic compounds; and sugars (e.g., glucose, fructose, sucrose, and rhamnose)	45	Karavaiko et al., 1995

Abbreviation: n.d., not determined.

There is also evidence that members of the genus *Acidianus* grow not only in continental solfatara fields but in other habitats as well (e.g., two strains of *A. infernus* have been isolated from geothermally heated submarine hydrothermal systems on the beach at Vulcano, Italy; Segerer et al., 1986).

Sulfolobus species are widespread and can be isolated from solfatara fields in a great number of geographically different locations, including the United States (Brock et al., 1972; Brock, 1978a), China (Xiang et al., 2003), Iceland (Brock, 1978a; Huber and Stetter, 1991a), Italy (DeRosa et al., 1974; Brock, 1978a; Zillig et al., 1980), Japan (Furuya et al., 1977; Yeats et al., 1982; Jan et al., 1999; Suzuki et al., 2002), New Zealand (Bohlool, 1975), and the West Indies (Brock, 1978a). In addition, strains were obtained from smoldering slag heaps at Ronneburg, Germany (Fuchs et al., 1995) and Kvarntorp, Sweden (H. Huber and O. Holst, unpublished observation). A recent study investigated the distribution of different strains of one species, "*S. islandicus*" (Whitaker et al., 2003). Although exhibiting identical 16S rRNA sequences, a small but significant level of genetic differentiation among the populations from Yellowstone National Park, Lassen Volcanic Park (Iceland), Uzon Caldera, and Mutnovsky Volcano was detectable.

Members of the genus *Acidianus* were isolated from solfataric springs in Naples, Italy (Segerer et al., 1986), the Yellowstone National Park, Wyoming, United States (Brierley and Brierley, 1973a; Segerer et al., 1986), Iceland (Segerer et al., 1986; Zillig et al., 1986), the Azores (Segerer et al., 1986), Java, Indonesia (Huber et al., 1991b), and the Southern Kurils, Russia (A. Segerer, unpublished observation).

Metallosphaera species have been found within Neapolitan solfataras (Huber et al., 1989), smoldering slag heaps at Ronneburg, Germany (Fuchs et al., 1995), and hot springs in Hakone, Japan (Takayanagi et al., 1996).

The only member of the genus *Stygiolobus* known so far, *St. azoricus*, was exclusively isolated from samples taken near Furnas and Ribeira Quente, Azores (Segerer et al., 1985; Segerer et al., 1991). It is still unclear whether this reflects geographic isolation.

Sulfurisphaera ohwakuensis has been obtained from acidic hot springs in Ohwaku Valley, Hakone, Japan (Kurosawa et al., 1998), while several *Sulfurococcus* species were isolated from a crater of the Uzon volcano in Kamchatka, Russia, and from a thermal spring in Yellowstone National Park, United States (Golovacheva et al., 1987a; Karavaiko et al., 1994).

Isolation

Nearly all members of the Sulfolobales can be cultivated within various low ionic strength media (see the section Medium for Cultivation in this Chapter) in the presence of elemental sulfur and at a pH around 3 (most strains will even grow at pH 1.5). The incubation temperature depends on the species but is usually above 75°C. Depending on the organism, aerobic or anaerobic conditions have to be applied (see media, section Medium for Cultivation). Several species are also able to grow on (complex) organic substrates.

Different representatives of the Sulfolobales quite often exhibit similar physiological features. Therefore, a selective enrichment of members of one genus or even one species is very hard to achieve.

Selective Enrichment of *Sulfolobus* and *Sulfurococcus* Species

Sulfolobus species can be enriched at 85°C in aerobic mineral medium supplemented with 0.1% (w/v) of yeast extract (exception *S. metallicus*). The high incubation temperature prevents growth of *Metallosphaera* strains and *Acidianus brierleyi*. *Acidianus infernus*, *A. ambivalens* and *Sulfurisphaera ohwakuensis* will not grow in this medium owing to the absence of sulfur or sulfide. *Stygiolobus azoricus* cannot grow under aerobic conditions. However, *Sulfurococcus* species will also be obtained under these enrichment conditions.

Selective Enrichment of Members of the Genus *Metallosphaera*

Metallosphaera sedula strains TH2 and TH4 have been selectively enriched with 0.33% (w/v) of pyrite, chalcopyrite, or ore mixture "G1N" as sole substrate at 65°C and pH 2 (Huber et al., 1989). The same conditions are suitable for *M. prunae* and *M. hakonensis*. A third *M. sedula* strain, SP3a, was enriched in the absence of ore on elemental sulfur in combination with yeast extract. The latter conditions are, however, not selective for *Metallosphaera* species.

Selective Enrichment of *Acidianus*, *Sulfurisphaera* and *Stygiolobus* Species

Highly anaerobic growth conditions (Balch et al., 1979) in medium supplemented with 0.02% (w/v) yeast extract in combination with about 0.5% (w/v) sulfur and an atmosphere consisting of H₂ and CO₂ (e.g., 80:20 [v/v], 300 kPa) allow the growth of facultatively or strictly anaerobic

members of the Sulfolobales, to the exclusion of *Sulfolobus*, *Metallosphaera* and *Sulfurococcus*.

Acidianus brierleyi is selectively enriched at 65°C, a temperature allowing only slow growth of the other species, with subsequent transfer into aerobic medium containing 0.1% (w/v) yeast extract, but no sulfur. *Acidianus infernus* and *A. ambivalens* are selectively enriched at 85°C, with subsequent transfer into aerobic culture medium containing 0.01% (w/v) yeast extract and 0.5% (w/v) sulfur. *Sulfurisphaera* grows under aerobic conditions heterotrophically.

Stygiolobus azoricus has been obtained from three anaerobically grown enrichment cultures (incubated at 85°C) by thrice-repeated end-point

dilution. As a characteristic, no growth is obtained after transfer to aerobic culture media.

Identification

Sulfolobales cells are coccoid, about 0.8–2 µm (rarely up to 5 µm) in diameter. Characteristically, they are highly irregular in shape and often strongly lobed or edged (Fig. 2A–C). The organisms stain Gram negative. All members of the Sulfolobales are extreme acidophiles, not growing above pH 5.5–6. They exhibit temperature optima between 60 and 90°C (Table 1).

Fig. 2. Electron micrograph of platinum-shadowed cells of A) *Sulfolobus acidocaldarius*; B) *Sulfolobus metallicus*; C) *Acidianus infernus*; bars for (A–C) are each 1 µm; D) electron micrograph of a freeze-etched cell of *Metallosphaera sedula*; bar is 1 µm; E) *Metallosphaera sedula* cell with flagellum; platinum-shadowed; bar is 1 µm; F) *Metallosphaera prunae* cells with flagella; platinum-shadowed; bar is 1 µm; and G) electron micrograph of freeze-etched cells of *Acidianus infernus*; bar is 1 µm.

With the exception of *Stygiolobus azoricus*, they are capable of aerobic growth on elemental sulfur, sulfur compounds, or organic material. In contrast, the extremely thermophilic to hyperthermophilic members of the order Thermoproteales are only moderately acidophilic, almost neutrophilic, and they exhibit exclusive rod-shaped morphologies (Huber and Stetter, 2001a; Huber et al., 2002b). Representatives of the Desulfurococcales are also almost neutrophiles and most of them grow under anaerobic conditions. They exhibit cell shapes from discs to irregular cocci (Huber and Stetter, 2001b; Huber and Stetter, 2002a). The extremely acidophilic members of the order Thermoplasmatales, which have been shown to occur also in solfataric springs (Seeger et al., 1988), can also be easily distinguished from the representatives of the Sulfolobales: They either lack a cell wall or possess an S-layer with p4-symmetry (genus *Picrophilus*), are strictly heterotrophic, and are incapable of sulfur oxidation (Huber and Stetter, 2001d).

Within the Sulfolobales, three distinct physiological groups are evident, allowing a rough but fast classification of an unknown strain (Table 1). There are 1) strictly aerobic sulfur-oxidizers, represented by members of the genera *Sulfolobus*, *Metallosphaera* and *Sulfurococcus*; 2) facultatively aerobic sulfur-oxidizers/reducers, represented by *Acidianus* and *Sulfurisphaera* species; and 3) the strictly anaerobic sulfur-reducing *Stygiolobus azoricus*. Further distinguishing features of the genera and species are listed in Table 1.

Sulfolobus cells are coccoid and differ from members of *Metallosphaera* by the highly irregular, lobed shape and the lower G+C content of their genomic DNA. The validly described species of the genus are phenotypically very similar to each other. They are distinguished by their different optimal and maximal growth temperatures, pH optimum, metabolism (Table 1), the DNA-dependent RNA polymerases, and mainly the 16S rRNA sequences (Zillig et al., 1979; Zillig et al., 1980; Fuchs et al., 1996; Huber and Stetter, 2001a). The cell wall is an S-layer (Weiss, 1974) located about 20 nm from the cytoplasmic membrane. It is attached to the membrane via as yet uncharacterized spacer proteins. The S-layer glycoprotein subunits are arranged on a two-dimensional crystalline lattice with p3 symmetry. The distance between the subunit complexes is around 20–21 nm. The three-dimensional structure of the S-layers from *S. acidocaldarius*, *S. solfataricus* and *S. shibatae* has been investigated in detail by electron crystallography (Taylor et al., 1982; Deatherage et al., 1983; Prüschen and Baumeister, 1987; Lembcke et al., 1991; Lembcke et al., 1993). Their fine structures are remark-

ably similar to each other and to the S-layer of *A. brierleyi* (Baumeister et al., 1991). They differ from the S-layers of genera of other crenarchaeal families and orders; therefore, at least in this phylum, “S-layer structures are of (limited) usefulness as taxonomic features” (Baumeister and Lembcke, 1992). Pilus- and pseudopodium-like appendages were found on cells attached to solid surfaces, e.g., sulfur crystals (Weiss, 1973; McClure and Wyckoff, 1982). They were also present in cells grown in liquid culture containing yeast extract (DeRosa et al., 1974). Flagella and flagella-like appendages have been described (Weiss, 1973; Typke et al., 1988; Grogan, 1989) and have also been observed in related species and genera (Fuchs et al., 1996; R. Rachel et al., unpublished observation; Fig. 2E, F). The cell membrane consists of isopranyl ether lipids (Langworthy, 1985; Langworthy and Pond, 1986; DeRosa and Gambacorta, 1988), some of which appear to be characteristic of Sulfolobales. These include: 1) a diglycerol tetraether containing a C₄₀ biphytanyl chain and two C₂₀ phytanyl chains (DeRosa et al., 1983); and 2) a glycerol-alkylnonitol tetraether, in which a branched C₉ nonitol trivially named “calditol” substitutes for a glycerol (DeRosa et al., 1980a). The membrane lipids are mainly composed of tetraethers containing up to four pentacyclic rings. The quantitative distribution of di- and tetraethers varies considerably with different species and growth parameters, e.g., temperature (DeRosa et al., 1980b), redox state (Langworthy and Pond, 1986), and nutrition (Langworthy, 1977). Further lipid compounds typical for Sulfolobales are unique sulfur-containing quinones. A benzo- $[\beta]$ -thiophen-4, 7-quinone named “caldariellaquinone” (DeRosa et al., 1977) and other unusual quinones (sulfolobus-quinone and tricyclic quinone) have been detected in some species.

Within the group of strict aerobes, members of the genus *Metallosphaera* are readily identified by their slightly lobed, coccoid cell shape and the G+C content of their genomic DNA (around 46 mol%; Table 1), which is the highest among the Sulfolobales. Growth occurs on sulfidic ores, on metal sulfides (characteristic for *M. hakonensis*: growth on FeS), and by oxidation of molecular hydrogen (not determined for *M. hakonensis*). No significant DNA-DNA homology was detected between *Metallosphaera* species and any other member of the Sulfolobales (Huber et al., 1989). The cell wall consists of an S-layer of glycoprotein subunits with p3 symmetry and a center-to-center distance of 21 nm (Fuchs et al., 1995; Fig. 2D). Flagella have been found, exhibiting a diameter of about 13 nm (Fig. 2E, F). Genome sizes of around 1.89 Mb have been determined for *Met-*

allosphaera sedula (Baumann et al., 1998), while the genomes of members of the genus *Sulfolobus* are significantly larger (Baumann et al., 1998; Kawarabayasi et al., 2001; She et al., 2001b). *Metallosphaera sedula* and *M. prunae* can be distinguished by the possession of a fibrillar surface coat and a significantly higher O₂ concentration requirement for growth on molecular hydrogen for *M. prunae* (Fuchs et al., 1995). No data for these characteristics are available for *M. hakonensis*.

Both *Sulfurococcus* species are reported to show a characteristic cell division by binary fission and budding; whether this feature differs from the mode of cell division in other members of the Sulfolobales is still an open question. All other characteristics are very similar to the *Metallosphaera* species, like morphology, metabolism, and G+C content of genomic DNA. Since no 16S rRNA sequences are available, the phylogenetic position of the *Sulfurococcus* species within the Sulfolobales is uncertain (the strains are not available!). Both organisms can be distinguished by their temperature optima and the ability to oxidize ferrous iron (Table 1).

In addition to their unique mode of energy conservation by either reduction or oxidation of elemental sulfur, a low DNA G+C content of ~31 mol% is characteristic for members of the genus *Acidianus*. Within this group, identification of *A. brierleyi* can easily be done by its growth temperature, which is the lowest known for any member of the Sulfolobales (Table 1). The strictly lithotrophic species *A. infernus* and *A. ambivalens* have, on the other hand, quite similar morphology, physiology, and genomic DNA G+C content (Seegerer et al., 1986; Zillig et al., 1986). They are best distinguished by their maximal growth temperature (Table 1). *Acidianus brierleyi* does not share significant DNA homology with *A. infernus* and *A. ambivalens*. No DNA homology was found with any other member of the Sulfolobales (Seegerer et al., 1986; Seegerer et al., 1991). The S-layer also exhibits p3 symmetry (Fig. 2G).

On the basis of 16S rRNA sequence comparisons, *Sulfurisphaera ohwakuensis* is phylogenetically very closely related to the *Sulfolobus* species *S. tokodaii* and *S. yangmingensis*. However, like the *Acidianus* species, it is a facultative anaerobic organism, although in contrast to them, it does not grow aerobically on sulfur compounds.

Stygiolobus azoricus is well characterized by its strictly anaerobic mode of life in combination with an obligate chemolithotrophic metabolism (S⁰-H₂ autotrophy). It shares no significant DNA homology with other members of the Sulfolobales (Seegerer et al., 1991).

Cultivation

Medium for Cultivation of All Sulfolobales Members
Basal Mineral Medium (Allen, 1959; modified by Brock et al., 1972)

(NH ₄) ₂ SO ₄	1.30 g
KH ₂ PO ₄	0.28 g
MgSO ₄ · 7H ₂ O	0.25 g
CaCl ₂ · 2H ₂ O	70 mg
FeCl ₃ · 6H ₂ O	20 mg
MnCl ₂ · 4H ₂ O	1.8 mg
Na ₂ B ₄ O ₇ · 10H ₂ O	4.5 mg
ZnSO ₄ · 7H ₂ O	0.22 mg
CuCl ₂ · 2H ₂ O	0.05 mg
Na ₂ MoO ₄ · 2H ₂ O	0.03 mg
VOSO ₄ · 2H ₂ O	0.03 mg
CoSO ₄	0.01 mg

Dissolve ingredients and dilute up to 1 liter with distilled water. Adjust pH to 2.0–3.0.

Although for a few members of the Sulfolobales (e.g., *Sulfurococcus*) slight modifications of this medium were applied for cultivation, all representatives can be grown in this medium.

Cultivation in Liquid Media

For heterotrophic growth, media are supplemented with organic substrates, for example, yeast extract (1 g/liter) or glucose (2 g/liter). For lithotrophic growth, media are supplemented with elemental sulfur (5–10 g/liter). Additional supplementation with low amounts (0.05–0.2 g/liter) of yeast extract or meat extract will provide significantly (about 10 times) better growth of most strains than is obtained by strictly autotrophic cultivation. Metal-mobilizing strains may be grown lithoautotrophically on a mixture of sulfidic ores (e.g., pyrite [Grube Bayerland, Germany], sphalerite [Grube Lüderich, Germany], chalcopryrite [Norway], and pitch blend [Grube Höhenstein, Germany]; Huber et al., 1986; Huber et al., 1989). A detailed chemical analysis of such an ore mixture is described in Huber et al. (1989).

The basal salt medium is sterilized by autoclaving. Organic components, elemental sulfur, or sulfidic ores are added afterwards from sterile stocks. Sterile sulfur is obtained by Tyndall's fractional sterilization procedure; sulfidic ores can be sterilized by dry incubation at 140°C for 15 h.

Aerobic cultivation is routinely carried out in long (e.g., 270 × 18 mm), aluminum-capped test tubes containing 10 or 15 ml of medium. Although the cultures have to be shaken, the comparatively small surface of medium provides microaerobic rather than fully aerobic growth conditions, the former being preferred by most strains. Alternatively, aerobic cultivation can occur in 100-ml Erlenmeyer flasks with shaking. Each flask contains 30 ml of

medium and is equipped with an air cooler (e.g., a 1-ml pipette tightly fitted through a rubber stopper). This procedure is especially recommended for lithoautotrophic strains on ores, but is also suitable for growing other *Sulfolobales* species.

Anaerobic media are prepared by using the technique of Balch et al. (1979). The media are reduced by the addition of Na_2S (0.75 g/liter). Cultivation is performed in rubber-stoppered 100-ml serum bottles containing 20 ml of medium plus sulfur and an atmosphere composed of H_2 and CO_2 (e.g., 80:20, 300 kPa). The bottles are sterilized by fractional sterilization and, if desired, supplemented with sterile organic substrate after the final cooling.

Members of the *Sulfolobales* may be fermented in conventional fermenters. However, special attention has to be paid to the very high corrosivity of both the medium and the metabolic products (H_2SO_4 and H_2S).

Cultivation on Plates

Sulfolobales cells may be plated onto medium solidified by Gellan gum K9A40 (Gelrite) (Zillig et al., 1986; Lindström and Sehlin, 1989), starch (R. Skorko, personal communication), or polysilicate (Stetter and Zillig, 1985). The use of agar is not recommended (Brock et al., 1972).

An overlay technique is used to plate facultatively and obligately heterotrophic strains and lithotrophic strains capable of efficiently growing by oxidation of soluble sulfur compounds (e.g., tetrathionate). A plating procedure based on Gelrite (Kelco Inc., San Diego, CA, United States) yielding plating efficiencies close to one is outlined by Lindström and Sehlin (1989). Gelrite suspension (1.6 g per liter in distilled water) is autoclaved (20 min, 121°C) and subsequently kept at $\geq 70^\circ\text{C}$ after autoclaving. Prewarmed double-strength mineral medium containing 20 mM tetrathionate, 2 mM NaCl, 0.2% yeast extract or Casamino AcidsTM, and 16 mM MgCl_2 is added to the Gelrite solution, mixed, poured into Petri dishes, and allowed to solidify. The soft gel contains half the concentration of Gelrite and is prepared similarly: double-strength medium containing the desired titer of bacteria is added to the liquid gel (0.8 g of Gelrite per liter), mixed, and poured onto the supporting gel. Plates can be incubated at 65°C in a sealed plastic bag or if available in stainless steel cylinders up to temperatures of 90°C to minimize evaporation.

Plating of obligately sulfur-dependent strains is still troublesome. Also in this case, a top layer technique rather than mechanical plating is advised. The following procedure was success-

fully used to obtain single colonies of *Acidianus infernus*.

Boil medium without sulfur and $(\text{NH}_4)_2\text{SO}_4$, containing 12% (w/v) of starch (Stärke Gel, Serva) and pour after dissolution of the polymer into Petri dishes. Allow these supporting gels to solidify and dry overnight at 4°C. To prepare one top layer, dissolve 20 mg of sulfur in a minimum amount of $(\text{NH}_4)_2\text{S}$ solution (20%; Merck, Darmstadt) to give a polysulfide solution, and dissolve 0.5 g of starch by boiling in 5 ml of medium, pH 5.5. After cooling the starch solution to about 45°C, add the highly alkaline polysulfide solution and a sufficient amount of 9N H_2SO_4 to give a final pH of 3. After combining the acidified starch medium and polysulfide, colloidal sulfur forms immediately. Vigorously mix this soft gel at once with the bacteria, pour onto the supporting gel, and allow to solidify at 4°C. Incubate plates microaerobically at 75°C in a pressure cylinder (Balch et al., 1979) or a desiccator containing a humid atmosphere of about 60% air and 40% CO_2 (v/v). Small, often slimy, ochreous-brown colonies will develop after 7 or more days of incubation.

Another plating procedure involving Gellan gum K9A40 (Scott) with colloidal sulfur derived from thiosulfate described by Zillig et al. (1986) was successfully used to plate *Acidianus ambivalens* under anaerobic conditions in an atmosphere consisting of H_2 and CO_2 .

Preservation

Members of the *Sulfolobales* maintain an intracellular pH of about 5.5 during growth (Lübben and Schäfer, 1989). To avoid damage to cells during storage caused by penetrating extracellular acid, addition of sterile CaCO_3 to raise the pH of all fully grown cultures to about 5.5 is recommended. Short-term storage is possible at 4°C. Although anaerobically grown strains are still sufficiently viable after one year of storage, maintenance requires transfer every 2–3 months. Anaerobically grown cells, e.g., *Acidianus infernus* cells, are significantly more resistant to storage at 4°C than are aerobically grown ones. Therefore, facultatively aerobic strains should be stored anaerobically.

Since oxygen is toxic to resting *Sulfolobus* cells (Grogan, 1989), storing cells under nitrogen significantly increases viability. Thus, storage under nitrogen at pH ~5.5 appears to be the most successful short-term storage procedure for aerobic members of the *Sulfolobales*.

Although not described for all strains, long-term storage is best achieved by freezing to around -140°C (in the gas phase over liquid nitrogen) cells suspended in culture media containing 5% dimethyl sulfoxide. No loss of cell viability is usually observed after storage of several years (H. Huber and D. Prangishvili, personal observation).

Physiology

As indicated above, all Sulfolobales species are extremely acidophilic thermophiles. With the exception of *Stygiolobus azoricus*, *Sulfurisphaera ohwakuensis* and a few *Sulfolobus* strains, all species can oxidize elemental sulfur to sulfuric acid according to the equation:

Modifications of this mode of energy conservation have been described. Oxygen can be replaced as an electron acceptor by MoO_4^{2-} (Brierley and Brierley, 1982) and Fe^{3+} (Brock and Gustafson, 1976a). Sulfur can be replaced as an energy source by S^{2-} (Brock, 1978a), $\text{S}_4\text{O}_6^{2-}$ (Wood et al., 1987), as well as by Fe^{2+} (Brierley and Brierley, 1973a; Brock et al., 1976b). Owing to their ability to oxidize sulfide, some strains are able to mobilize metals from sulfidic ores by formation of soluble sulfates (Brierley, 1978; Huber et al., 1986; Huber et al., 1989; Huber and Stetter, 1991a; Karavaiko et al., 1994; Fuchs et al., 1995; see also the section Applications). In addition, growth by oxidation of molecular hydrogen ("Knallgas reaction") is possible for many Sulfolobales (Huber et al., 1992). However, significant differences in the optimal oxygen concentrations for this metabolism were observed in the investigated strains.

Several species and strains are able to grow on CO_2 as sole carbon source (Shivvers and Brock, 1973; Wood et al., 1987; Huber et al., 1989; Huber and Stetter, 1991a; Segerer et al., 1991). Assimilation of carbon dioxide was first studied with *A. brierleyi*. In the beginning it was thought that the fixation occurs via a reductive carboxylic acid pathway (Kandler and Stetter, 1981). However, by measuring enzymatic activities, key enzymes of the 3-hydroxypropionate cycle were detected in autotrophically grown cells, which led to the conclusion that a modified 3-hydroxypropionate pathway operates in *A. brierleyi* (Ishii et al., 1997). In detailed studies, the enzymes of this pathway were identified also in other autotrophically grown cells of Sulfolobales species (Menendez et al., 1999; Hügler et al., 2003a) and finally the key enzyme for carboxylation (acetyl-CoA/propionyl-CoA carboxylase) was identified as the main CO_2 fixation enzyme for the autotrophic members of the Sulfolobales (Hügler et al., 2003b).

Several representatives of the Sulfolobales (e.g., *A. brierleyi* and some *Sulfolobus* or *Metallosphaera* species) are facultative heterotrophs, capable of growing on various complex organic substrates like yeast extract, meat extract, bacterial extracts, peptone, tryptone, or Casamino Acids™. *Sulfolobus* species also grow well on various mono-, oligo-, and even polymeric sugars

and amino acids (Brock et al., 1972; DeRosa et al., 1975; Brock, 1978a; Grogan, 1989). Many strains of Sulfolobales may grow mixotrophically (Wood et al., 1987). Interestingly, the type strains of *S. acidocaldarius* DSM 639 and *S. solfataricus* DSM 1616 have become incapable of oxidizing sulfur, as evidenced by observations in independent laboratories (Marsh et al., 1983; Huber et al., 1989). They apparently have mutated into obligately heterotrophic strains.

Aerobic growth of strictly or facultatively aerobic members of the Sulfolobales is often enhanced at low oxygen tensions and with an atmosphere enriched with 5% (v/v) CO_2 (Brock, 1978a; Stetter and Zillig, 1985; H. Huber, personal observations), indicating that the organisms are microaerophiles. This finding is consistent with their sensitivity to H_2O_2 and the aerophobic response of *Sulfolobus* species (Grogan, 1989).

Representatives of the genera *Acidianus* and *Sulfurisphaera* can both oxidize and reduce molecular sulfur (Segerer et al., 1985; Zillig et al., 1985; Kurosawa et al., 1998). Anaerobic growth occurs via $\text{S}^0\text{-H}_2$ autotrophy (Fischer et al., 1983) and large amounts of H_2S are formed (equation 2):

This mode of energy conservation operates also in the strictly anaerobic *Stygiolobus azoricus*.

Biochemistry and Molecular Biology

A huge number of biochemical and molecular biology studies has been performed with various strains of Sulfolobales. However, these investigations have not been extended to all members.

RESPIRATORY CHAIN Within the Sulfolobales, fairly complete respiratory chains and individual respiratory catalysts have been characterized mainly from *S. acidocaldarius*, *S. metallicus*, *S. tokodaii* and *A. ambivalens* by identifying their components using absorption spectroscopy of intact cells, membranes, or detergent-solubilized complexes (e.g., Anemüller et al., 1985; Lübben et al., 1986; Wakagi and Oshima, 1987; Iwasaki et al., 1995a; Iwasaki et al., 1995b; Gomes et al., 1998a; Bandejas et al., 2003; see also the review by Schäfer et al., 1999). The so far simplest aerobic respiratory chain was detected in *A. ambivalens*: it is composed of a type-II reduced nicotinamide adenine dinucleotide (NADH) dehydrogenase (Gomes et al., 2001), a succinate:quinone oxidoreductase (Gomes et al., 1999; Lemos et al., 2001), caldariella quinone, and a single terminal quinol oxidase of the *aa*₃ type (Giuffrè et al., 1997; Purschke et al., 1997).

In contrast, *S. acidocaldarius* has a much more intricate respiratory chain: it is a split electron transport chain. Two different terminal oxidase complexes exist, the so-called “SoxABCD complex” (Lübben et al., 1992; Castresana et al., 1995) and the “SoxM supercomplex” (Lübben et al., 1994; Castresana et al., 1995; see review by Schäfer et al., 1999). In *S. metallicus*, the major NADH dehydrogenase appears to be the type-II enzyme with unique features: the flavin group is covalently bound and contains a flavin mononucleotide instead of a flavin dinucleotide (Bandeiras et al., 2003). Furthermore, the spectroscopic analysis of the respiratory chain revealed the presence of a novel type of iron sulfur cluster and indicated the presence of several respiratory enzymes (Gomes et al., 1998b). So far, the presence of the respiratory NADH dehydrogenase, the essential component of bacterial respiratory chains (Complex I), has not been detected in Sulfolobales (Schäfer et al., 1999; She et al., 2001b).

Sulfolobales species contain unique types of quinones that are part of the respiratory chain of Sulfolobales. Beside caldariella quinone (CQ; DeRosa et al., 1977; Collins and Langworthy, 1983), benzo- $[\beta]$ -thiophen-4,7-quinone, called “sulfolobus quinone” (SQ), was found in considerable amounts in *A. infernus* and *A. ambivalens*, but only in traces in *S. acidocaldarius* (Thurl et al., 1986). Whereas aerobically grown cells of *A. ambivalens* contain only about one-third of the SQ amount found in anaerobically grown cells, *A. infernus* contains no SQ when grown aerobically and no CQ when grown anaerobically. As in eukaryotes, the aromatic portion of CQ is derived from tyrosine. *Sulfolobus* strain MT 4 contains a tricyclic benzo[1,2- β ; 4,5- β']dithiophen-4,8-quinone (Lanzotti et al., 1986), which is absent in *Metallosphaera sedula* (Huber et al., 1989). In *S. solfataricus*, the ratio between *Sulfolobus* quinone and caldariella quinone was reported to vary considerably with growth temperature (Nicolaus et al., 1992).

Activity of a coenzyme A-acylating 2-oxoacid:ferredoxin oxidoreductase was detected in cell-free extracts of *S. acidocaldarius* (Kerscher et al., 1982). A ferredoxin probably containing two $[4\text{Fe-4S}]^{2+(2+,1+)}$ clusters per molecule, which had an apparent molecular mass of 12.7 kDa, was purified from this organism (Kerscher et al., 1982), and its amino acid sequence has been determined (Minami et al., 1985). In addition, $[3\text{Fe-4S}]$ clusters in the form of di-cluster seven-iron ferredoxins were found within the Sulfolobales. Their ferredoxins are small, monomeric proteins with β -sheet structure that contain one $[3\text{Fe-4S}]^{+/0}$ center and one $[4\text{Fe-4S}]^{2+/+}$ center (Teixeira et al., 1995; Gomes et al., 1998a). Parameters that affect the linear cluster

formation and disassembly in *S. acidocaldarius* have been investigated (Jones et al., 2002).

Further elements of the respiratory chain of *S. acidocaldarius* consist of different *a*- and *b*-type cytochromes (Anemüller et al., 1985; Anemüller and Schäfer, 1989). In contrast, it is still an open question whether enzymes or analogs to the cytochrome bc_1 complex (or the closely related b_6f complex) can be found in the membranes of Sulfolobales. At present there is only indirect evidence for the existence of archaeal homologues to these complexes. Genes encoding Rieske proteins and *b*-type cytochromes have been detected in the genomes of different *Sulfolobus* species (e.g., Kawarabayasi et al., 2001; She et al., 2001b). A novel type of iron cluster, which may act as a functional of Rieske iron-sulfur proteins, was found in *S. metallicus* (Gomes et al., 1998b).

Membrane-bound ATPases have been isolated from *S. acidocaldarius* DSM 639 (Lübben and Schäfer, 1987a; Lübben et al., 1987b; Schäfer and Meyering-Vos, 1992a; Schäfer and Meyering-Vos, 1992b), *S. solfataricus* (Hochstein and Stan-Lotter, 1992), *S. tokodaii* and *A. ambivalens* (Hinrichs et al., 1999). The A_1 ATPase of *S. acidocaldarius* released from the plasma membrane has an apparent molecular mass of 380 kDa and consists of four subunits of 65, 51, 20 and 12 kDa (Lübben et al., 1987b). The membrane-bound ATPase from *S. tokodaii* has a different apparent molecular mass of 360 kDa and consists of subunits of 69, 54 and 28 kDa, respectively (Wakagi and Oshima, 1985; Konishi et al., 1987).

SULFUR METABOLISM The sulfur oxidation pathway has been studied with *A. ambivalens* as the model organism (recently reviewed in Kletzin et al., 2004). A soluble sulfur oxygenase reductase (SOR) catalyzes the initial step of S^0 oxidation by performing a sulfur disproportionation reaction with sulfite, thiosulfate and hydrogen sulfide as the products (Kletzin, 1989). The colorless SOR, both native and recombinant, showed the presence of a low-potential mononuclear iron site ($E_m = -270$ mV). Electron microscopy showed that the enzyme forms a hollow, (bacterio-) ferritin-like sphere of 15.5 nm in diameter which is most probably composed of 24 identical subunits made of dimer building blocks (Urich et al., 2004).

The product thiosulfate is oxidized to tetrathionate by a novel type of quinone-containing, thiosulfate:quinone oxidoreductase purified from the membrane fraction (Müller et al., 2004). The 102-kDa glycoprotein was composed of two subunits with apparent molecular masses of 28 and 16 kDa, which were previously thought to be part of the terminal oxidase (DoxD and DoxA; Purschke et al., 1997). The enzyme

has an optimum activity at 85°C and pH 5 (Müller et al., 2004). Thiosulfate-dependent oxygen consumption inhibitable by addition of cyanide indicates that this reaction is one of the entry points of electrons into the electron transport chain. The fate of the tetrathionate is not clear at present.

The other SOR product (sulfite) is oxidized by two different pathways (Zimmermann et al., 1999). A membrane-bound sulfite:acceptor oxidoreductase activity was found. It is also oxidized by soluble enzymes involving an adenylylsulfate adenylyltransferase and an adenosine phosphosulfate reductase leading to energy conservation by substrate-level phosphorylation. The enzymes have not yet been purified in both cases.

Sulfur reduction was studied by Laska and Kletzin (2000) and Laska et al. (2003) in *A. ambivalens*. The purification and biochemical and molecular characterization of the membrane-bound hydrogenase and sulfur reductase from cells grown under anaerobic conditions were reported.

SUGAR DEGRADATION Glucose metabolism in *Sulfolobus solfataricus* strain MT 4 and *S. acidocaldarius* was investigated and shown to occur exclusively via a modified Entner-Doudoroff (ED) pathway not involving phosphorylated intermediates and producing pyruvate (DeRosa et al., 1984; Bartels 1989; Selig et al., 1997). This pyruvate is finally almost completely converted to CO₂; no three-carbon fermentation products and no significant amounts of acetate are formed. The CO₂ is generated via acetyl-CoA (by pyruvate-ferredoxin oxidoreductase) and the tricarboxylic acid (TCA) cycle. The net ATP yield of this nonphosphorylated ED pathway is zero, but ATP can be generated from reduced pyridine nucleotides oxidized by molecular oxygen in the respiratory chain (Schönheit and Schäfer, 1995). However, on the basis of analysis of the *S. solfataricus* genome, it was proposed that instead of reduced nicotinamide adenine dinucleotide phosphate (NAD[P]H), ferredoxin may act as the main physiological electron carrier (She et al., 2001b). Several metabolic enzymes involved in catabolism, intermediary metabolism, and anabolism have been investigated, partially or totally purified, and characterized. These include β -galactosidase (Buonocore et al., 1980), pyridine-dependent glucose dehydrogenase (Giardina et al., 1986), NAD⁺-dependent alcohol dehydrogenase (Rella et al., 1987), malic enzyme (Bartolucci et al., 1987; Guagliardi et al., 1988), aspartate aminotransferase (Marino et al., 1988), and propylamine transferase (Cacciapuoti et al., 1986) from *S. solfataricus* strain MT 4, citrate synthase from *S. acidocaldarius* and *S. solfataricus* (Großebüter and Görisch, 1985; Löhlein-

Werhan et al., 1988), and isocitrate dehydrogenase (Danson and Wood, 1984) and malate dehydrogenase (Görisch et al., 1985; Hartl et al., 1987) from *S. acidocaldarius*.

SUGAR STORAGE AND ACCUMULATION As occurs in other Archaea (e.g., *Pyrobaculum aerophilum* or *Thermoplasma acidophilum*), the cells of the Sulfolobales accumulate trehalose (Nicolaus et al., 1988; Martins et al., 1997). The function of trehalose as a possible osmolyte within the Sulfolobales (which are organisms that grow in media with very low salt concentrations) is highly unlikely (Martins et al., 1997) and remains unknown.

In *Sulfolobus shibatae*, glycogen of an average chain length of only seven glucose molecules was isolated and in complexes with four proteins, one of which was identified as a glucosyl-transferase using both ADP-glucose and UDP-glucose as substrates (König et al., 1982).

SOLUTE TRANSPORT PROTEINS A whole range of sugar ATP-binding cassette (ABC) transporters has been found in *S. solfataricus* (Albers et al., 1999; Elferink et al., 2001). These transporters fall into two groups: 1) the glucose, arabinose, trehalose-systems, which show similarity to the sugar ABC transporters of bacteria, and 2) the cellobiose and maltose and maltotriose transporters, which exhibit the highest similarity to bacterial di- and oligopeptide transporters.

URIDINE-5'-MONOPHOSPHATE BIOSYNTHESIS Screening of different nucleic acid precursors for their ability to incorporate into nucleic acids of heterotrophically growing *S. acidocaldarius* indicated predominance of the de novo over the "salvage" pathway of pyrimidine nucleotide biosynthesis (Muskhelishvili et al., 1990). The result was confirmed by genetic studies (Grogan and Gunsalus, 1993).

SULFOLOBICINS Several strains of "*S. islandicus*" produce proteinaceous toxins with molecular mass of 20 kDa, termed "sulfolobocins," which kill cells of other strains of the same species as well as strains of *S. solfataricus* and *S. shibatae*, but not *S. acidocaldarius* (Prangishvili et al., 2000). They were associated with the producer cells as well as with cell-derived S-layer-coated spherical membrane vesicles 90–180 nm in diameter and not released from cells in soluble form (Prangishvili et al., 2000).

CHROMATIN AND CHROMOSOME STRUCTURE In different strains of *Sulfolobus* a reverse gyrase was found, an enzyme that introduces positive superturns into DNA at the expense of ATP and is specific for hyperthermophilic archaea

(reviewed by Forterre et al. [1996] and Forterre [2000]). *Sulfolobus* strains also contain a type II topoisomerase which relaxes both positive and negative superturns and exhibits a strong decatenase activity (reviewed by Forterre et al., 1996). It is a heterotetramer composed of two subunits, one of which is homologous to the factor Spo11 required for initiation of meiotic recombination in the Eukarya (Bergerat et al., 1997).

Among several DNA binding proteins found in Sulfolobales, the most abundant are proteins of two families. One of them is the Sso7d family (recently renamed the “Sul7d family” by White and Bell, 2002) of small architectural proteins, specifically found only in *Sulfolobus* strains. Proteins were reported to stabilize the double helix from denaturation (Baumann et al., 1994), to promote the annealing of complementary strands (Guagliardi et al., 1997), and to show ATPase-dependent rescue of aggregate proteins (Guagliardi et al., 2000). Binding of these proteins causes unwinding of the helix and negative supercoiling (Agback et al., 1998; Lopez-Garcia et al., 1998; Mai et al., 1998; Robinson et al., 1998) as well as DNA bending and compaction (Napoli et al., 2002). The role of these proteins *in vivo* is not understood. It has been suggested that they are involved in homeostatic control of DNA superhelicity in Sulfolobales (Lopez-Garcia et al., 1998).

Members of another family of abundant DNA-binding proteins of *Sulfolobus* are known which induce negative supercoiling. They are named “Ssh10,” “Sso10b,” and “Sac10b,” depending on the species of origin (Lurz et al., 1986; Forterre et al., 1999; Xue et al., 2000). This protein, found also in many other Archaea and some Eukarya, has been recently named “Alba” (for “acetylation lowers binding affinity”) because it is found acetylated *in vivo* and is deacetylated by the *Sulfolobus* homolog of the eukaryal histone deacetylase Sir2 (Bell et al., 2002). Deacetylation of Alba reduces its affinity for DNA and its ability to repress transcription and suggests similarities in modulation of chromatin activity by acetylation in Archaea and Eukarya. A model for the Alba-DNA interaction consistent with the available structural data has been suggested (Wardleworth et al., 2002).

DNA TRANSCRIPTION, REPLICATION, REPAIR AND RECOMBINATION Studies on transcription in *Sulfolobus* species started with a purification of an RNA polymerase (Zillig et al., 1979). Complexity of the enzyme, consisting of at least 10 subunits, was much higher than of bacterial RNA polymerases and resembled that of RNA polymerase II of Eukarya. Subsequent bioinformatic and biochemical studies on *Sulfolobus* transcription machinery have confirmed that it resembles

the core components of the eukaryal RNA polymerase II apparatus and showed that it uses also bacterial-like gene-specific transcription regulators (reviewed by Bell and Jackson, 2001). Briefly, RNA polymerase together with a TATA-binding protein (TBP) and transcription factor B (TFB), homologues of the eukaryal transcription factors TBP and TFIIB, respectively, is sufficient to direct initiation of transcription on promoters that contain a TATA box and transcription factor B recognition element (BRE), reminiscent of eukaryal RNA polymerase II promoters.

As mentioned above (see the section Chromatin and Chromosome Structure in this Chapter), in clear parallel to eukaryotes, *Sulfolobus* species possess the capacity to modulate transcription through covalent modification of a key chromatin protein. Neither of the two chromatin proteins, Sul7d (Napoli et al., 2002) or Alba (Wardleworth et al., 2002), has in its native state an effect on a reconstituted *in vitro* transcription. However, acetylation of the latter protein significantly lowers its affinity for DNA and results in repression of transcription (Bell et al., 2002).

The existence of a global gene regulatory system in *S. solfataricus* involving activation is suggested by the coordinated transcription of three physically unlinked glycosyl hydrolase genes in response to change in carbon source (Haseltine et al., 1999). However, elements of this system remain to be elucidated.

The presence of multiple forms of DNA polymerases in *Sulfolobus* cells was first demonstrated biochemically (Prangishvili, 1986) and later confirmed by results of genome sequencing. Three enzymes, PolB1, PolB2 and PolB3, belong to family B of DNA polymerases (She et al., 2001b). The replicative polymerase B1 has been most intensively studied (Klimczak et al., 1985; Rossi et al., 1986; Bukhrashvili et al., 1989; Chinchaladze et al., 1989; Elie et al., 1989; reviewed by Böhlke et al., 2002). *Sulfolobus* possesses also a DNA polymerase belonging to the Y family, which apparently is specialized in the replication of aberrant DNA templates and is able to bypass certain DNA lesions in an error-free manner (Kulaeva et al., 1996; Boudsocq et al., 2001; Gruz et al., 2001; Kokoshka et al., 2002; Potapova et al., 2002). The structural basis of lesion bypass has been investigated by crystallographic approaches utilizing PolY from different strains of *S. solfataricus* (Ling et al., 2001; Silvian et al., 2001; Zhou et al., 2001).

The activity of PolB1 is stimulated and its processivity is enhanced by the sliding clamp, proliferating cell nuclear antigen (PCNA), a heterotrimer of three distinct subunits, PCN1, 2 and 3 (Dionne et al., 2003). The finding is in marked

contrast to a report by De Felice et al. (1999) that indicated that high concentrations of individual PCNA1 and PCNA3 could stimulate the polymerase. The heterotrimeric PCNA besides DNA polymerase stimulates the activities of DNA ligase I and the flap endonuclease. A model for clamp loading of PCNA has been suggested by unique subunit-specific interactions between components of the clamp loader, the replication factor C (Dionne et al., 2003).

Studies on the single-stranded DNA-binding protein (SSB) of *S. solfataricus* have suggested that it represents a simplest form of SSB protein studied to date and demonstrated striking similarity of its structure to that of human replication protein A (Wadsworth and White, 2001; Kerr et al., 2003).

Repair of double-stranded breaks in DNA in *Sulfolobus* appears similar to its eukaryal equivalent. In the pathway of homologous recombination, the recombinase that causes strand exchange, RadA, of *S. solfataricus* is significantly more similar in sequence to eukaryal Rad51 than to the eubacterial RecA protein (Sandler et al., 1996) and has the same DNA binding and pairing preferences as its homologues (Seitz and Kowalczykowski, 2000). The processing of DNA ends at the initiation step of homologous recombination in *S. acidocaldarius* involves four proteins Rad50, Mre11, NurA and HerA, the genes of which constitute an operon; the latter two proteins are prototypes of new families of nucleases and helicases, correspondingly (Elie et al., 1997; Constantinesco et al., 2002; Constantinesco et al., 2004). Two distinct Holliday junction resolvases, Hjc and Hje, with differing substrate specificities have been described for *S. solfataricus* (Kvaratskhelia et al., 2000). Hjc has no recognizable branch migration motor for the Holliday junction. Its activity in vitro is stimulated by the chromatin protein Sul7d (Kvaratskhelia et al., 2002). The three-dimensional structure of Hjc revealed extensive structural homology with a superfamily of type II restriction enzymes (Bond et al., 2001).

In nucleotide excision repair in *S. solfataricus*, a structure-specific endonuclease is involved which is homologous to eukaryal nuclease XPF and has the substrate specificity remarkably similar to the human XPF but displays an unexpected requirement for a functional interaction with the sliding clamp PCNA (Roberts et al., 2003; see above).

TRANSLATION For translation initiation in *S. solfataricus*, apparently different mechanisms are used. This was indicated by the finding of a Shine-Dalgarno sequence upstream of the genes inside operons but not generally for the first gene in an operon or isolated genes (Tolstrup et al.,

2000). This finding was later confirmed biochemically (Benelli et al., 2003). Shine-Dalgarno-dependent initiation, resembling the pathway prevalent in extant bacteria, apparently operates on distal cistrons of polycistronic mRNAs, whereas "leaderless" initiation, reminiscent of the eukaryotic pathway, operates on monocistronic mRNAs and on opening cistrons of polycistronic mRNA (Benelli et al., 2003).

In *Sulfolobus* species, small RNAs were found and functionally characterized. Almost all of these are related to the plethora of small RNAs that form the core of the complex ribonucleoprotein machinery responsible for eukaryotic ribosome biosynthesis and mediate diverse, complex and essential processes such as intron excision, RNA modification and editing, protein targeting, etc. (reviewed by Tang et al. [2002] and Omer et al. [2003]).

Translation inhibition by many specific antibiotics in cell free extracts of several Sulfolobales species was investigated by Sanz et al. (1994). The analysis showed that the ribosomes of Sulfolobales were the most refractory to inhibitors of protein synthesis known so far.

CELL CYCLE REGULATION As revealed by epifluorescence microscopy and flow cytometry, the chromosomal DNA in *S. solfataricus* is differently organized in exponentially growing and stationary cells, and it is conceivable that DNA-binding proteins of different classes are involved in this reorganization (reviewed by Bernander, 2000). Within the *Sulfolobus* cell cycle there was found a G2 period, similar to that in the eukaryotic cell cycle, during which cells increase in size (until they reach the desired mass or size for segregating the genomes) and then divide (Hjort and Bernander, 2001). Synchronous cell cycle progression in *S. acidocaldarius* could be generated by daunomycin treatment (Hjort and Bernander, 2001) or by dilution of stationary phase culture into fresh medium (Hjort and Bernander, 1999). Abrupt temperature shifts were shown to induce cell cycle arrest and chromosomal DNA degradation (Hjort and Bernander, 1999).

HEAT SHOCK Little is known on the general heat-shock response in Sulfolobales. It was shown that in "*S. islandicus*," the control of DNA topology during stress relies primarily on the physical effect of temperature on topoisomerase activities and on the geometry of DNA itself (Lopez-Garcia and Forterre, 1999).

In *S. shibatae*, acquired thermotolerance at lethal temperatures ($\geq 90^{\circ}\text{C}$) correlates with the increased synthesis of two heat-shock proteins known as "TF55 α and β " (Trent et al., 1990; Trent et al., 1994; Kagawa et al., 1995). These proteins are isolated from cells as subunits of

Electron micrographs of representatives of different families of viruses of *Sulfolobales*, negatively stained with uranyl acetate: A) Lipothrixvirus SIFV of *Sulfolobus* (reproduced from Arnold et al. [2000b], with permission). B) Lipothrixvirus AFV1 of *Acidianus* (reproduced from Bettstetter et al. [2003], with permission). C) Rudivirus SIRV1 of *Sulfolobus*. D) Fusellovirus SSV2 of *Sulfolobus*. E) “Guttavirus” of *Sulfolobus* (courtesy of Wolfram Zillig). Bars are 200 nm; for insets in A), B), and C), bars are 100 nm.

double-ring complexes called “rosettosomes” that share structural and functional features with chaperonins (Trent et al., 1991). They constitute up to 4% of total cellular protein and in vitro can generate a filamentous structure (Trent et al., 1997). Under all conditions, rosettosomes were shown to be membrane-associated, and their function as a membrane skeleton that interacts with lipids and/or membrane-associated proteins to impact the permeability and stability of the cytoplasmic membrane has been suggested (Trent et al., 2003).

Extrachromosomal Genetic Elements

Extrachromosomal genetic elements described for members of the order *Sulfolobales* include about a dozen of viruses and about two dozen of plasmids, conjugative and cryptic.

Viruses

The unusual features of viruses of *Sulfolobales* warranted the establishment of novel virus fam-

ilies: spindle-shaped enveloped Fuselloviridae, enveloped lipid-containing filamentous *Lipothrixviridae*, and unenveloped, stiff-rod-shaped Rudiviridae (Prangishvili, 1999b; reviewed by Prangishvili et al., 2001). The fourth family, the *Guttaviridae*, has been suggested but not yet approved for the bearded-droplet-shaped virus (Arnold et al., 2000a). The structure of virus particles from each of the families is shown in Fig. 3A–E and virus properties are summarized in Table 2. In addition to these cultivated viruses, a plethora of virus-like particles was found to be produced by different strains of *Sulfolobales* (reviewed in Prangishvili, 2003).

Viruses of *Sulfolobus* are exceptional also in characteristics of virus-host interactions. In contrast to nearly all double-stranded (ds)DNA prokaryotic viruses which eventually kill the host cell during release of progeny virions, *Sulfolobus* viruses establish a productive infection without killing or lysing the cell, a so-called “carrier state.” Only in one case of the *Sulfolobus* virus SSV1 has there been observed induction of virus production in the lysogenic strain but without subsequent cell lysis. In all cases, the infected cells continue to replicate themselves as well as the virus, although cellular growth is slowed

Table 2. Viruses of Sulfolobales.

Families	Species	Host	ds DNA (kb)	Peculiarities of genome	References
<i>Fuselloviridae</i>	SSV1	<i>S. shibatae</i> , <i>S. solfataricus</i> , “ <i>S. islandicus</i> ”	Circular (15.5)	Positively supercoiled	Schleper et al., 1992 ^a Palm et al., 1991 ^b Stedman et al., 2003 ^b

down, suggesting inhibition of some specific cell functions.

Double-stranded DNA genomes of several viruses have been sequenced. These include circular genomes of the fuselloviruses SSV1 and SSV2 (Palm et al., 1991; Stedman et al., 2003), linear genomes of lipothrixviruses SIFV (Arnold et al., 2000b) and AFV1 (Bettstetter et al., 2003) and linear genomes of ruidiviruses SIRV1 and SIRV2 (Peng et al., 2001). About 90% of all open reading frames (ORFs) on sequenced genomes show no significant matches to sequences in public databases, suggesting that viruses of *Sulfolobales* have exceptional biochemical solutions for biological functions. Genomes share some homologous genes, and they yield good sequence matches with genes present in the host chromosomes. They include genes encoding glycosyl transferases, CopG family proteins, integrases, dUTPases and Holliday junction resolvases as well as proteins of unknown function (reviewed in Prangishvili and Garrett, 2004); some of these enzymes have been biochemically characterized (Muskhelishvili et al., 1993; Prangishvili et al., 1998; Birkenbihl et al., 2001). None of the viruses share homologous ORFs with viruses of other prokaryotes.

Specific features of genome organization, as well as strategies for DNA replication, suggest phylogenetic relationships between the ruidiviruses of *Sulfolobus* and the large eukaryal DNA viruses: poxviruses, the African swine fever virus, and *Chlorella* viruses (Blum et al., 2001; Peng et al., 2001). Sequence patterns at the ends of the linear genome of the lipothrixvirus AFV1 are reminiscent of the telomeric ends of linear eukaryal chromosomes and suggest that a primitive telomeric mechanism operates in this virus (Bettstetter et al., 2003).

Plasmids

Twelve cryptic circular plasmids (5.3–7.6 kb in size) have been isolated from different strains of *Sulfolobus* and *A. ambivalens* (Zillig et al., 1998). Among them five plasmids have been sequenced: pRN1 (Keeling et al., 1996), pRN2 (Keeling et al., 1998), pSSVx (Arnold et al., 1999), and pHEN7 (Peng et al., 2000) from “*S. islandicus*” strains and pDL10 (Kletzin et al., 1999) from *A. ambivalens*. Sequence comparison revealed that all five plasmids belong to the same family (Peng et al., 2000) and do not resemble known bacterial plasmids. The plasmids share three conserved ORFs arranged in identical order and orientation on all plasmids. The corresponding proteins of the plasmid pRN1 have been heterologously expressed and biochemically

characterized. Two of them (6.5 and 9.5 kDa) are sequence-specific DNA-binding proteins, and the smaller is believed to participate in regulating the copy number (Lipps et al., 2001a; Lipps et al., 2001b). The third protein is a unique multifunctional enzyme with primase, DNA polymerase, and DNA-dependent ATPase activity (Lipps et al., 2003). The N-terminal half of the protein harbors a novel domain which is able to polymerize DNA without the need of a separate priming enzyme. There is no sequence similarity to other known DNA polymerases and primases, suggesting that this protein constitutes a new DNA polymerase family.

Several families of conjugative plasmids hosted by a *Sulfolobus* sp. from Japan and different strains of “*S. islandicus*” have been described (Schleper et al., 1995; Prangishvili et al., 1999a). Mechanism of conjugation has not been elucidated. Plasmids contain only two ORFs with some sequence similarity to genes essential for conjugation in the Bacteria, *traG* and *trbE* (She et al., 1998; Stedman et al., 2000).

Genetics

Genomic Sequences

Nucleotide sequences of the 3 Mb genome of *S. solfataricus* strain P2 (She et al., 2001b; the sequence and annotation are also available on the Homed at LBMGE website (<http://www-archbac.u-psud.fr>, www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide&search=AE006641) and of the 2.7 Mb genome of *S. tokodaii* (Kawarayashi et al., 2001) the sequence and annotation are also available on the National Institute of Technology and Evaluation website (<http://www.bio.nite.go.jp>) have been determined. In progress is sequencing of the genomes of *S. acidocaldarius*, “*S. islandicus*” strain HVE10/4 (R. A. Garrett, personal communication), *A. ambivalens* (A. Kletzin, personal communication) and *A. brierleyi* (Q. She, personal communication).

Genome Stability and Mutants

Two main types of mobile elements identified on the *S. solfataricus* genome are the autonomous insertion sequence (IS) elements (Brügger et al., 2002) and the nonautonomous miniature inverted repeat elements (Redder et al., 2001). They are considered to be mobilized via transposases encoded by IS elements, constitute about 10% of the genome, and are spread out along it, however, mainly clustered in two areas separated by putative replication origin and ter-

mination regions. Such an abundance of mobile elements gives the *S. solfataricus* genome a high level of plasticity. Transposon mutagenesis apparently is a dominant mechanism of mutation in this organism. Transposition of several distinct families of IS elements into the β -galactosidase gene and at the chromosomal *pyrEF* locus was shown to produce spontaneous *lacS*⁻ and uracyl auxotrophic mutants, correspondingly, with high frequencies (Schleper et al., 1994; Martusewitsch et al., 2000).

There is strong evidence that DNA can enter and leave chromosomes of at least some Sulfolobales, facilitated by an integrase (reviewed by She et al., 2002). This was first demonstrated for the virus SSV1 which encodes an integrase facilitating insertion into the tRNA^{Arg} gene in the chromosome of the host, *S. shibatae* (Muskhelishvili et al., 1993). During insertion, the integrase gene is partitioned into two fragments which flank the linearized virus DNA in the chromosome. Both gene fragments carry perfect direct repeats, and excision involves recombination at these direct repeats. Similarly partitioned integrase genes occur in chromosomes of other members of the Sulfolobales. For example, in *S. solfataricus*, one borders an inserted plasmid (Peng et al., 2000) and another a large (67 kb) integron-like segment (She et al., 2001a).

High genome plasticity is not typical for all Sulfolobales. *Sulfolobus acidocaldarius* has few active IS elements (Grogan et al., 2001; R. A. Garrett, personal communication). According to mutational analysis of the *pyrE* and *pyrF* genes, *S. acidocaldarius* has one of the lowest genomic error rates yet measured (Grogan et al., 2001). Moreover, it was shown that within the low mutant frequency, deletions make up an unusually low proportion of spontaneous mutations (Grogan and Hansen, 2003b).

Several *lacS*⁻ and uracyl auxotrophic mutants of *S. acidocaldarius* and *S. solfataricus*, as well as thermosensitive mutants of *S. acidocaldarius*, have been isolated and characterized (Grogan, 1991; Kondo et al., 1991; Grogan and Gunsalus, 1993; Schleper et al., 1994; Bernander et al., 1998; Martusewitsch et al., 2000; Bartolucci et al., 2003). As a result of disruption of the gene encoding a secreted α -amylase of *S. solfataricus*, a mutant strain was produced unable to grow on starch, glycogen or pullulan as sole carbon and energy source (Worthington et al., 2003).

ing conjugative plasmids and virus DNAs are used for construction of vectors. A derivative of the conjugative plasmid pNOB8 containing a *lacS* gene as a selectable marker has been used for transformation of *lacS*⁻ mutant of *S. solfataricus* and complementation of *lacS* activity (Elferink et al., 1996). DNA of the virus SSV1 provides a basis for ongoing vector construction. A shuttle vector has been constructed by introducing an *E. coli* plasmid into the nonessential region of the viral genome (Stedman et al., 1999). Upon transfection, this vector spreads efficiently throughout the culture. Development of other recombinant SSV1-based shuttle vectors has resulted in complementation of uracyl auxotrophic and β -galactosidase mutants of *Sulfolobus* (Jonuscheit et al., 2003).

A stable *E. coli*/*S. solfataricus* shuttle vector was constructed also by introduction of the replication sequence of the virus SSV1 into an *E. coli* plasmid (Cannio et al., 1998). Using this vector as a cloning vehicle, functional complementation of *lacS*⁻ mutants defective in β -glycosidase activity was demonstrated (Bartolucci et al., 2003). The same vector was used for the gene transfer and expression in *S. solfataricus* of two genes of thermophilic bacteria (Contursi et al., 2003). The selectable system used in these experiments has been developed by adaptation of the hygromycin B phosphotransferase from *E. coli* to high temperatures, allowing resistance to the antibiotic hygromycin and selection in *Sulfolobus* (Cannio et al., 2001).

A plasmid of *Pyrococcus abyssi*, pGT5, has also been used as a basis for transformation protocols for *Sulfolobus* (Aravalli and Garrett, 1997). A vector containing its replication origin and an *adh* gene from *S. solfataricus* could propagate in both *Pyrococcus furiosus* and *S. solfataricus*. The system uses as selection markers toxic alcohols such as butanol that are detoxified by the plasmid-encoded *Sulfolobus adh* gene and the selection provided is weak. The potential of the mobile intron from *Desulfurococcus mobilis*, inserted into an *E. coli* plasmid, to generate a new type of vector was demonstrated in *S. acidocaldarius* (Aagaard et al., 1996). A gene replacement method was used to disrupt an α -amylase coding sequence by insertion of a modified allele of the *S. solfataricus lacS* gene and to produce mutant recombinant strain (Worthington et al., 2003).

Tools for Genetic Manipulation

Transformation protocols reported for *Sulfolobus* are not yet fully suitable and require further improvement. In some cases, efficiently spread-

Restriction-Modification System

Restriction-modification system, designated “*SuaI*,” with a recognition sequence GGCC, has been biochemically characterized for *S. acidocal-*

darius (Prangishvili et al., 1985). It uses N⁴ methylation of the inner C to protect the recognition sequence from restriction (Grogan, 2003a).

Ecology

Representatives of the Sulfolobales thrive in acidic biotopes with original temperatures from at least 50°C to about 100°C. They are typical inhabitants of high-temperature continental solfataric areas and have been isolated from such biotopes nearly worldwide. They share these habitats with other thermophilic and hyperthermophilic organisms, including members of the orders Desulfurococcales, Thermoproteales, Thermoplasmatales, and Aquificales. They can be enriched from the aerobic and anaerobic zones of solfataric soils, which can be easily identified owing to the different colors caused by oxidized or reduced iron. Depending on the volcanic activity and exhalation of reducing volcanic gases (e.g., H₂S and H₂), the anaerobic zone starts at a depth of a few centimeters up to about 50 cm below the oxidized layers (Huber et al., 2000). In marine hydrothermal systems, members of the Sulfolobales seem to be extremely rare.

In their ecosystems, members of the Sulfolobales can function as primary producers and/or as consumers of organic material. For the chemolithoautotrophic primary producers, oxygen and elemental sulfur (for anaerobes) are suitable electron acceptors for growth. Different sulfur compounds or molecular hydrogen serve as the electron donors. The end product of their metabolism is H₂SO₄, H₂O or H₂S; in addition, the organic cell material is formed. The heterotrophs consume organic matter by growth via respiration or fermentation with single organic compounds (e.g., sugars and proteins) or complex organic substrates (e.g., yeast extract, peptone, and meat extract). Therefore, the Sulfolobales are important for the carbon cycle in acidic high temperature habitats.

Biotechnology

By means of sulfide oxidation, several isolates of Sulfolobales are able to extract metal ions from sulfidic ores ("bioleaching"; Brierley and Murr, 1973b; Brierley, 1978; Marsh et al., 1983; Huber et al., 1986; Huber et al., 1989; Huber and Stetter, 1991a; Fuchs et al., 1995). Whereas some strains only mobilize metal ions weakly, others, e.g., *Metallosphaera* species and *Sulfolobus metallicus*, are very efficient ore leachers (Huber et al., 1986; Huber et al., 1989; Huber and Stetter, 1991a; Fuchs et al., 1995). Thus, they may be

suitable for reactor or in situ leaching of geothermally heated ore deposits.

Immobilized cells of *Sulfolobus* strain MT 4 were used for studying production of glucose and 2-keto-3-deoxygluconate at self-sterilizing reactor temperatures (Drioli et al., 1982; Drioli et al., 1986; Nicolaus et al., 1986; Catapano et al., 1988).

Sulfolobales strains have also been investigated for use in the removal of inorganic and organic sulfur from coal and oil (Kargi and Robinson, 1985; Kargi, 1987; Chen and Skidmore, 1988).

Acknowledgments. The authors thank G. Gmeinwieser for technical support and R. Rachel for electron microscopy.

Desulfurococcales

HARALD HUBER AND KARL O. STETTER

Introduction

The order Desulfurococcales (Huber and Stetter, 2001b) is one of three orders of the archaeal phylum Crenarchaeota (Woese et al., 1990), which also includes Thermoproteales (Huber and Stetter, 2001a) and Sulfolobales (Stetter, 1989). Cells of members of the Desulfurococcales are regular to irregular cocci, discs or dishes, which occur singly, in pairs, short chains, or grapelike aggregates. Diameters of coccoid cells vary from about 0.5 up to 15 μm , while disc-shaped cells frequently exhibit ultra-flat areas only about 0.1 to 0.2 μm thick. All members of the order Desulfurococcales are hyperthermophiles with optimal growth temperatures between 85 and 106°C. They grow anaerobically, facultatively anaerobically, or aerobically. Under autotrophic conditions, they gain energy by oxidation of hydrogen using elemental sulfur, thiosulfate, nitrate, or nitrite as electron acceptor, and they use CO_2 as a carbon source. Alternatively, organotrophic growth occurs by aerobic respiration or anaerobic sulfur respiration or by fermentation of organic substrates. Following the classification listed in the new edition of *Bergey's Manual of Systematic Bacteriology* (Huber and Stetter, 2001b), the order Desulfurococcales comprises two validly published families, the Desulfurococcaceae (Zillig et al., 1982; Burggraf et al., 1997) and the Pyrodictiaceae (Burggraf et al., 1997). The members of these two families can be physiologically distinguished by their optimal and maximal growth temperatures: the Desulfurococcaceae harbor organisms which grow optimally between 85 and 95°C and exhibit temperature maxima up to 102°C. In contrast, the Pyrodictiaceae are characterized by optimal growth temperatures between 95 and 106°C and temperature maxima between 108 and 113°C. Furthermore, several members of this family form a network of hollow tubules (cannulae).

The term “sulfur-dependent” archaeobacteria (now Archaea) was formerly used to designate the branch which is now the phylum Crenarchaeota. However, several members of the Desulfu-

rococcales are obligate organotrophs and are unable to use elemental sulfur or sulfur compounds for energy formation; some strains and species are even inhibited by the presence of elemental sulfur. Therefore, the designation “sulfur-dependent” Archaea (“Archaeobacteria”) should not be used anymore.

In the former edition of *The Prokaryotes* (Huber and Stetter, 1992), only the family Desulfurococcaceae (Zillig et al., 1982) with the genus *Desulfurococcus* and the genera *Pyrodictium* (Stetter, 1982; Stetter et al., 1983), *Thermodiscus* (Stetter and Zillig, 1985; Stetter, 2001), and *Staphylothermus* (Fiala et al., 1986) had been mentioned and placed within the order Thermoproteales because of their physiological properties (Huber and Stetter, 1992). Meanwhile, mainly on the basis of 16S rRNA sequence comparisons, these genera have been placed either within the Pyrodictiaceae (*Pyrodictium*), Desulfurococcaceae (*Thermodiscus* and *Staphylothermus*) or within the novel order Desulfurococcales (Huber and Stetter, 2001b). Furthermore, several new genera have been described.

Phylogeny

On the basis of 16S rDNA sequence comparisons, the order Desulfurococcales represents one lineage of the crenarchaeotal branch of the Archaea (Woese et al., 1990; Fig. 1). It forms a separate cluster and is distinct from the two other orders described so far, the Sulfolobales and the Thermoproteales. The representatives of the Desulfurococcales exhibit phylogenetic similarities of 0.89–1.00 to members within the order and 0.89–0.79 to all other species of the Crenarchaeota. These values indicate that the order is clearly defined by 16S rRNA gene sequence comparisons. The two described families, the Desulfurococcaceae and the Pyrodictiaceae, are also obvious from these results (Fig. 1). The phylogenetic position of *Acidilobus acetatus* is not absolutely clear; however, in most calculations it branches within the family of the

Fig. 1. Phylogenetic tree based on 16S rRNA sequences. The tree was calculated using the maximum likelihood program, which is included in the (ARB package; Ludwig and Strunk, 2001). Scale bar: 10 estimated exchanges within 100 nucleotides. Red lines = Desulfurococcales; blue lines = Thermoproteales; yellow lines = Sulfolobales; and green lines = Euryarchaeota.

Desulfurococcaceae (Fig. 1). All members of the order, particularly the Pyrodictiaceae, are characterized by very short lineages in the corresponding phylogenetic trees (Fig. 1). Since the organisms form a cluster around the root of the 16S rRNA-based phylogenetic tree, hyperthermophiles appear to be primitive (Stetter, 1995).

Phylogenetic investigations based on analyses of partial 23S rRNA sequences were carried out by Kjems et al. (1992). The resulting phylogeny, although less comprehensive, was generally consistent with the 16S rRNA tree.

Taxonomy

The order Desulfurococcales was defined recently by Huber and Stetter (2001b) in the last edition of *Bergeys Manual of Systematic Bacteriology*. However, this name had already been proposed in the last edition of *The Prokaryotes* (Huber and Stetter, 1992). The description of the family Desulfurococcaceae (Zillig et al., 1982) was emended by Burggraf et al. (1997). In the same paper, the family Pyrodictiaceae was validly described, although the name “Igneoococcales” was proposed in this publication to designate the order. At present, the Desulfurococcales are comprised of two families: the Desulfurococcaceae harbor nine validly published genera, while the Pyrodictiaceae are represented by three genera (Prokofeva et al., 2000; Huber and Stetter, 2001b). Furthermore, the 16S rRNA gene sequence of “*Caldococcus noboribetis*” has been published, although a description of this organism has not (Aoshima et al., 1996a).

The genus *Desulfurococcus* (Zillig et al., 1982), the type genus of the family Desulfurococ-

caceae and the order Desulfurococcales, harbors three validly described species: *D. mucosus* (Zillig et al., 1982), *D. mobilis* (Zillig et al., 1982) and *D. amylolyticus* (Bonch-Osmolovskaya et al., 1988; validated: 2001: ISJEM 51, 1619–1620), and the so far not validly described “*D. saccharovorans*” (Stetter, 1986; Table 1). The type strain for *D. mucosus* is strain 07^T (American Type Culture Collection [ATCC 35584^T], Deutsche Sammlung von Mikroorganismen und Zellkulturen [DSM 2162^T] and Japan Collection of Microorganisms [JCM 9187^T]), the type strain for *D. mobilis* is strain Hv3^T (ATCC 35582^T, DSM 2161^T and JCM 9186^T), and for *D. amylolyticus* is strain Z-533^T (DSM 3822^T and JCM 9188^T). The species are characterized by optimal growth temperatures between 85 and 90°C, an anaerobic mode of life, and the capability of sulfur respiration with complex organic substrates or fermentation of peptides. They can be distinguished by their substrates used and their motility.

Within the family of the Desulfurococcaceae, seven other genera have been described:

1) *Aeropyrum* (Sako et al., 1996; type species: *A. pernix*; type strain K1^T, JCM 9820^T), 2) *Ignicoccus* (Huber et al., 2000a; type species: *I. islandicus*; type strain Kol8^T, DSM 13165^T; further species: *I. pacificus*; type strain LPC33^T, DSM 13166^T), 3) *Staphylothermus* (Fiala et al., 1986; type species: *S. marinus*; type strain F1^T, DSM 3639^T and ATCC 49053^T; further species: *S. hellenicus*; type strain P8^T, DSM 12710^T and JCM 10830^T; Arab et al., 2000), 4) *Stetteria* (Jochimsen et al., 1997; type species: *S. hydrogenophila*; type strain 4ABC^T, DSM 11227^T), 5) *Sulfophobococcus* (Hensel et al., 1997; type species: *S. zilligii*; type strain K1^T, DSM 11193^T and JCM 10309^T),

Table 1. Characteristics of the Desulfurococcals species.

	Cell size Cell surface Flagellation	Temp (°C) (opt. °C)	pH range (pH opt.)	NaCl conc. (opt. %)	Relation to oxygen	Biotores	Metabolism	Energy yielding reactions	G+C content (mol %)	References
<i>Desulfurococcus mucosus</i>	Cocci, Ø 0.3–2.0 µm, sometimes up to 10 µm Mucoid layer of neutral sugars Not flagellated	76–93 (85)	4.5–7.0 (6.0)	n.d. (around 0)	Anaerobic	Continental	Mixotrophic or heterotrophic	Sulfur respiration or fermentation using complex organic components	51	Zillig et al., 1982
<i>Desulfurococcus mobilis</i>	Cocci, Ø 0.5–1.0 µm S-layer, p4 symmetry Polytrichous flagellated	78–87 (8.5)	n.d. (6.0)	n.d. (around 0)	Anaerobic	Continental	Mixotrophic or heterotrophic	Sulfur respiration or fermentation using complex organic components	51	Zillig et al., 1982
<i>Desulfurococcus amylolyticus</i>	Cocci, Ø 0.7–1.5 µm S-layer, symmetry? Not flagellated	68–97 (90–92)	5.7–7.5 (6.4)	n.d. (around 0)	Anaerobic	Continental	Heterotrophic S ⁰ stimulates growth	Fermentation using peptides, amino acids, starch, or glycogen	42	Bonch- Osmolovskaya et al., 1988
<i>Aeropyrum pernix</i>	Cocci, Ø 0.8–1.0 µm S-layer, p4 symmetry Motile without flagella (?)	70–100 (90–95)	5.0–9.0 (7.0)	1.8–7.0 (3.5)	Aerobic	Marine	Heterotrophic	Aerobic respiration with O ₂ of complex organic compounds	67 (56)	Sako et al., 1996 Kawarabayashi et al., 1999
<i>Ignicoccus islandicus</i>	Cocci, Ø 1.2–3 µm Outer sheath Polytrichous flagellated	70–98 (90)	3.8–6.5 (5.8)	0.3–5.5 (2.0)	Anaerobic	Marine	Obligate lithoautotrophic	S ⁰ -H ₂ autotrophy	41	Huber et al., 2000a
<i>Ignicoccus pacificus</i>	Cocci, Ø 1.0–2.0 µm Outer sheath Polytrichous flagellated	75–98 (90)	4.5–7.0 (6.0)	1.0–5.0 (2.0)	Anaerobic	Marine	Obligate lithoautotrophic	S ⁰ -H ₂ autotrophy	45	Huber et al., 2000a
<i>Staphylothermus marinus</i>	Cocci, Ø 0.5–1.5 µm, up to 100 cells in aggregates S-layer, p4 symmetry Not flagellated	65–98 (92)	4.5–8.5 (6.5)	1.0–3.5 (1.5)	Anaerobic	Marine	Heterotrophic S ⁰ -required	Fermentation of complex organic compounds	35	Fiala et al., 1986
<i>Staphylothermus hellericus</i>	Cocci, Ø 0.8–1.3 µm, in large aggregates n.d. Single flagellum	70–90 (85)	4.5–7.0 (6.0)	2.0–8.0 (4.0)	Anaerobic	Marine	Heterotrophic S ⁰ -required	Fermentation of complex organic compounds	38	Arab et al., 2000

<i>Stetteria hydrogenophila</i>	Cocci, Ø 0.5–1.5 µm n.d. Single flagellum	68–102 (95)	4.5–7.0 (60)	0.5–0.6 (2.0–4.0)	Anaerobic	Marine	Mixotrophic, H ₂ and S ⁰ (S ₂ O ₃ ²⁻) required	S ⁰ , S ₂ O ₃ ²⁻ respiration with H ₂ and complex organic compounds	65	Jochimsen et al., 1997
<i>Sulfophobococcus zilligii</i>	Cocci, Ø 3–5 µm n.d. Tuft of filaments	70–95 (85)	6.5–8.5 (7.5)	0–0.2	Anaerobic	Continental	Obligate heterotrophic	Growth by fermentation, only on yeast extract	55	Hensel et al., 1997
<i>Thermodiscus maritimus</i>	Dish to disc-shaped cocci; Ø 0.3–3 µm n.d. Not flagellated	75–98 (90)	5.0–7.0 (5.5)	1.0–4.0 (2.0)	Anaerobic	Marine	Obligate heterotrophic	Sulfur respiration and fermentation of complex organic compounds	49	Stetter, 2001
<i>Thermosphaera aggregans</i>	Cocci, Ø 0.2–0.8 µm in aggregates Amorphous layer Up to eight flagella	65–90 (85)	5.0–7.0 (6.5)	0–0.7 (0.4)	Anaerobic	Continental	Obligate heterotrophic	Fermentation of complex organic compounds	46	Huber et al., 1998
<i>Pyrodicticum occultum</i>	Discs and dishes, Ø 0.3–2.5 µm × 0.2 µm S-layer, p6 symmetry	85–100 (105)	4.5–7.2 (5.5)	0.2–12 (1.5)	Anaerobic	Marine	Chemolithoautotrophic to Mixotrophic	S ⁰ , S ₂ O ₃ ²⁻ -H ₂ autotrophy	62	Stetter, 1982 Stetter et al., 1983
<i>Pyrodicticum abyssi</i>	Formation of a network Discs, Ø 1–2 µm S-layer, p6 symmetry	80–110 (97)	4.7–7.1 (5.5)	0.7–4.2 (2)	Anaerobic	Marine	Obligate heterotrophic	Fermentation of complex organic compounds	60	Pley et al., 1991
<i>Pyrodicticum brockii</i>	Formation of a network Discs and dishes, Ø 0.3–2.5 µm × 0.2 µm S-layer, p6 symmetry	n.d. (105)	4.5–7.2 (5.5)	0.2–12 (1.5)	Anaerobic	Marine	Chemolithoautotrophic to Mixotrophic	S ⁰ , S ₂ O ₃ ²⁻ -H ₂ autotrophy or growth on complex organic compounds	62	Stetter et al., 1983
<i>Hyperthermus butylicus</i>	Formation of a network Cocci, Ø 1.5 µm S-layer, p6 symmetry Not flagellated	72–108 (95–106)	n.d. (7.0)	n.d. (1.7)	Anaerobic	Marine	Obligate heterotrophic	Fermentation of peptides	56	Zillig et al., 1990
<i>Pyrolobus fumarii</i>	Cocci, Ø 0.7–2.5 µm S-layer, p4 symmetry Not flagellated	90–113 (106)	4.0–6.5 (5.5)	1.0–4.0 (1.7)	Anaerobic/ microaerobic	Marine	Obligate chemolithoautotrophic	Nitrate, S ₂ O ₃ ²⁻ or O ₂ reduction with H ₂	53	Blöchl et al., 1997
<i>Acidilobus acetatus</i>	Cocci, Ø 1–2 µm S-layer with osmophilic layer– Not flagellated	60–92 (85)	2.0–6.0 (3.8)	n.d. (0)	Anaerobic	Continental	Obligate heterotrophic	Fermentation of complex organic compounds	54	Prokofeva et al., 2000

Symbols and abbreviations: –; Ø = cell diameter; and n.d., not determined.

6) *Thermodiscus* (Stetter, 2001; type species: *T. maritimus*; type strain S2^T, DSM 15173^T and JCM 11597^T), and 7) *Thermosphaera* (Huber et al., 1998; type species: *T. aggregans*; type strain M11TL^T, DSM 11486^T).

In addition to *I. islandicus* and *I. pacificus*, a third strain of *Ignicoccus* was isolated recently from the Kolbeinsey Ridge, north of Iceland (strain KIN4/I). This strain is the host of *Nanoarchaeum equitans*, the first representative of a new phylum of Archaea (Huber et al., 2002).

Furthermore, the genus *Acidilobus* (Prokofeva et al., 2000; type species: *A. aceticus*; type strain 1904^T, DSM 11585^T) can be attached to this family, although on the basis of 16S rDNA sequence similarities, it is not closely related to the other genera. The closest relative to *Acidilobus* is "*Caldococcus noboribetus*" (Aoshima et al., 1996a); however, this organism was never validly described or deposited in culture collections.

The main characteristics for distinguishing these genera are summarized in Table 1. *Aeropyrum*, the only obligate aerobe within the family, gains energy by respiration of organic substrates. *Ignicoccus* is an obligate chemolithoautotroph (S⁰-H₂ autotrophy) and produces exclusively H₂S as the metabolic end product. *Staphylothermus* cells grow in aggregates and gain energy by fermentation of complex organic substrates in the presence of elemental sulfur. They exhibit a low G + C content of their genomic DNA (35–38 mol%). The major characteristic of the genus *Stetteria* is its growth by sulfur respiration with complex organic substrates and its strict requirement of molecular hydrogen. *Sulfophobococcus*, as implied by the name, is inhibited by elemental sulfur. *Thermodiscus* is characterized by disk-shaped cells, which carry out sulfur respiration with complex organic substrates. *Thermosphaera* forms short chains or aggregates and is inhibited not only by elemental sulfur but also by molecular hydrogen. *Acidilobus* exhibits a pH optimum at 3.8 and is therefore, along with "*Caldococcus*," the only acidophile within the group. Furthermore, all genera are clearly defined by the results of 16S rDNA sequence comparisons implemented in the corresponding phylogenetic trees (e.g., Fig. 1).

The Pyrodictiaceae represent the second family within the order Desulfurococcales. It consists of three genera, *Pyrodictium* (Stetter et al., 1983), *Hyperthermus* (Zillig et al., 1991), and *Pyrolobus* (Blöchl et al., 1997). The genus *Pyrodictium*, the type genus of the family, harbors three species: *P. occultum* (the type species for the genus; Stetter et al., 1983), *P. abyssi* (Pley et al., 1991), and *P. Brockii* (Stetter et al., 1983). The type strain of *P. occultum* is strain PL-19^T (DSM 2709^T), of *P. abyssi*, strain AV2^T (DSM 6158^T), and of *P. Brockii*, strain S1^T (DSM

2708^T). The characteristic feature of the *Pyrodictium* species is the formation of a network of hollow cannulae, in which the coccoid or disk-shaped cells are embedded. The organisms are obligate anaerobes with temperature optima between 97 and 105°C. The species can be distinguished by their growth substrates and cell envelope composition.

Hyperthermus butylicus (Zillig et al., 1990; type strain DSM 5456^T), the only representative of the genus, is an obligate anaerobe that grows by fermentation of proteolysis products, forming organic acids, butanol, and CO₂.

Pyrolobus fumarii (Blöchl et al., 1997; type strain 1A^T, DSM 11204^T) is a facultatively anaerobic, obligately chemolithoautotrophic, irregular coccus which exhibits the highest temperature maximum of all life forms on earth, 113°C.

Habitats

Members of the Desulfurococcales have been found worldwide in biotopes of volcanic activity on land, in shallow marine areas, and in the deep sea. Representatives of the genera *Desulfurococcus*, *Sulfophobococcus*, *Thermosphaera* and *Acidilobus* have been isolated from hot springs, water and mud holes, and soils of continental solfataric fields with low salinity and acidic to slightly alkaline pH values, such as occur in the Askja-, Hveravellir-, and Hveragerdi areas in Iceland, the Uzon Caldera, Valley of Geysers, and Mendelev Volcano (on Kamchatka and Kunashir Island, Russia), and the Yellowstone National Park (United States). They are adapted to these low ionic strength biotopes as indicated by their NaCl optima (Table 1).

Strains of the genera *Aeropyrum*, *Ignicoccus*, *Staphylothermus*, *Stetteria*, *Thermodiscus*, *Pyrodictium* and *Hyperthermus* have been obtained from shallow marine high temperature sediments, springs, and venting waters (original temperatures up to 112°C) at Kodakara-Jima Island (Japan), Kolbeinsey Ridge (north of Iceland, depth 105 m), Vulcano Island (Italy), Paleohori Bay (Milos, Greece), and Sao Miguel Island (Azores). *Ignicoccus*, *Staphylothermus*, *Pyrodictium* and *Pyrolobus* have been isolated from deep-sea hydrothermal systems and black smoker fragments at the East Pacific Rise (9–11° N and 21° N, depth 2500 m), the Guaymas Basin hot vent area (27° N, depth 2000 m), and the Mid-Atlantic Ridge (TAG site [geographical landmark]: 26° N, depth 3650 m). *Pyrodictium* has been also found in the active zone of an erupting submarine volcano (Macdonald Seamount, Indonesia; Huber et al., 1990).

Isolation

Enrichment

All representatives of the Desulfurococcales are hyperthermophiles; therefore, enrichment at temperatures of at least 85°C is highly selective. Representatives of the genera *Desulfurococcus*, *Sulfophobococcus*, *Thermosphaera* and *Acidilobus*, which thrive in continental solfataric areas, can be enriched in low-salt media (see Media for Cultivation) prepared by the use of the anaerobic techniques of Balch and Wolfe (1976). The media are supplemented with elemental sulfur and/or various kinds of complex or defined organic substrates with a gas phase of N₂, H₂/CO₂, and N₂/CO₂ (80:20, v/v, 200–300 kPa) at incubation temperatures around 85°C. Depending on the species, peptides, amino acids, glycogen, starch, glucose, or acetate can serve as carbon sources during sulfur respiration or fermentation. *Acidilobus* can be selectively enriched in media with pH 3.

Members of the genera *Aeropyrum*, *Ignicoccus*, *Staphylothermus*, *Stetteria*, *Thermodiscus*, *Pyrodictium*, *Hyperthermus* and *Pyrolobus* grow in artificial seawater based media (see Media for Cultivation). They are adapted to the ionic strength of their natural habitats, which is expressed by optimal growth at NaCl concentrations between 2 and 3%. For *Aeropyrum* enrichment at 95°C in an aerobic medium in the presence of molecular oxygen is successful. *Pyrodictium*, *Hyperthermus* and *Pyrolobus* can be selectively obtained by incubation at temperatures of around 105°C. A highly selective enrichment method for *Pyrolobus* is the use of nitrate as the sole electron acceptor in addition. *Ignicoccus* can be obtained in a medium without organic components.

Isolation Procedures

Anaerobic, microaerobic, or aerobic culture media are inoculated with 0.5–1 ml (or grams) of the environmental samples. The culture attempts should be checked by phase-contrast microscopy over a period of up to several weeks for growth. The isolates are obtained from the enrichment cultures by serial dilution (three times) or by plating. The plates can be solidified by 0.6–0.8% Gelrite and colonies are visible after 4–14 days. However, successful plating is not reported for every member of the Desulfurococcales. A recently developed isolation technique that is safe, fast and suitable for organisms unable to grow on solidified media is the use of the “optical tweezers” trap (also see Thermoproteales in this Volume; Huber et al., 1995).

Identification

Members of the Desulfurococcales are regular to irregular coccoid to disc- or dish-shaped cells with diameters from 0.2 to 15 µm (Table 1). They do not divide by septa formation, and spores are not formed. All members stain Gram negative. In most species the cell envelope is composed of an S-layer, i.e., glycoprotein subunits regularly arranged on a two-dimensional lattice, with four- or sixfold symmetry. Alternatively, an outer membrane or an amorphous layer can occur; muramic acid is always absent. The DNA-dependent RNA polymerase is of the “BAC” type and the transcription is resistant to rifampicin and streptolydigin. The major core lipids are glycerol dialkylglycerol tetraethers and 2,3-di-*O*-phytanyl-*sn*-glycerol. The G+C contents of genomic DNA range from 35 to 67 mol% (Table 1). The Desulfurococcales are anaerobic, facultatively anaerobic or aerobic organisms with optimal growth temperatures between 85 and 106°C and therefore harbor the organisms with the highest temperature maxima known so far (108–113°C; see also Physiology). With the exception of *Acidilobus* and “*Caldococcus*,” they grow in a pH range of 4.5–9 with an optimum around 5–7.0.

Cells of *Desulfurococcus* are regular spheres usually between 0.5 and 1 µm in diameter (Fig. 2a), although cells of up to 10 µm may occur. *Desulfurococcus mucosus* is surrounded by a mucoid layer, which covers the envelope and consists of neutral sugars and a small fraction of amino sugars (Stetter and Zillig, 1985). In contrast, *D. mobilis* is devoid of this mucous polymer. Instead, as indicated by the name, it possesses a bundle of up to seven flagella (diameter 12.5 nm) attached at one pole of the cell (Fig. 2b). *Desulfurococcus* species possess an S-layer with fourfold symmetry and a center-to-center distance of 18 nm (investigated for *D. mobilis*; Wildhaber et al., 1987). It is built up of protein complexes in the shape of a cross. The S-layer encloses a periplasmic space about 30 nm wide. An intron was found in the 23S rRNA sequence of *D. mobilis* (Larsen et al., 1986). The G+C content of the genomic DNA is 51 mol% for *D. mobilis* and *D. mucosus*, while it is only 42 for *D. amylolyticus* (Table 1).

Aeropyrum pernix cells are irregular cocci with diameters of 0.8 to 1 µm, sometimes exhibiting sharp edges. In contrast to their original description, cells are highly motile and possess flagella (Fig. 3a). In the genome, two flagellin genes were detectable (Thomas et al., 2001). *Aeropyrum pernix* has pili-like appendages. The cell envelope consists of an S-layer with fourfold symmetry and a center-to-center distance of

18 nm (R. Rachel, unpublished observation; Fig. 3b). The original G+C content of the genomic DNA was determined to be 67 mol%; however, sequencing of the whole genome revealed only 56 mol% (Kawarabayashi et al., 1999). The core lipids of *A. pernix* consist of di-esterterpanyl (C25, C25) glycerol ether lipids. Five components of polar lipids were detected; phosphoglycolipid (archaetidyl [glucosyl] inositol, containing inositol and glucose) and phospholipid (archaetidyl inositol) are predominant (Morii et al., 1999). *Aeropyrum pernix* possesses two family B DNA polymerases (Cann et al.,

1999), and the 16S–23S rRNA operon contains three introns (Nomura et al., 1998).

All *Ignicoccus* cells are slightly irregular cocci with diameters of 1–3 μm . They are monopolar polytrichously flagellated (Fig. 4a). They exhibit a unique cell architecture within the Archaea: a cytoplasmic membrane; a periplasmic space with a variable width of 20 up to 400 nm containing membrane-bound vesicles; and an outer membrane, approximately 10 nm wide (Fig. 4b). The outer membrane contains three different types of particles: numerous tightly, irregularly packed single particles about 8 nm in size; pores with

Fig. 5. Electron micrograph of *Staphylothermus marinus* cells; platinum-shadowed. Bar = 1 μ m.

diameters of 24 nm surrounded by tiny particles arranged on a ring with a diameter of 130 nm; and clusters of up to 8 particles, each 12 nm in size (Fig. 4c). Freeze-etched cells exhibit a smooth surface, without a regular pattern, indicating the absence of an S-layer (Fig. 4c); frequently, fracture planes through the outer membrane are found (Rachel et al., 2002). The G+C content, of the two described species are 41 and 45 mol%, respectively (Table 1). The core lipids of *I. islandicus* are acyclic 2,3-di-*O*-phytanyl-*sn*-glycerol and glyceroldialkyl glycerol tetraether in a relative ratio of 1 : 1 (Huber et al., 2000a).

Cells of both *Staphylothermus* species are regular to slightly irregular cocci, about 0.8–1.3 μ m in diameter. They often form aggregates (Fig. 5), sometimes containing up to 100 cells. In the presence of high concentrations of yeast extract (0.2%) in the medium, *S. marinus* forms giant cells of up to 15 μ m in diameter. They contain at least one dark granulum (about 1 μ m in diameter), which most likely consists of glycogen. The cell envelope of *Staphylothermus* consists of an almost 70 nm wide periplasm and an S-layer of a poorly ordered meshwork of branched, filiform morphological subunits, named “tetrabrachion.” Tetrabrachion is a glycoprotein tetramer that forms a parallel, four-stranded α -helical rod, separated at one end into four strands (Peters et al., 1995). An extremely thermostable protease is tightly bound in stoichiometric amounts to this structure (resistant to heat inactivation up to 125°C in the stalk-bound form; Mayr et al., 1996). Both *Staphylothermus* species (*S. marinus* and *S. hellenicus*) exhibit a low G+C content of the genomic DNA of 35 and 38 mol%, respectively.

Stetteria cells are irregular to disc-shaped cocci with a diameter of 0.5–1.5 μ m. The cells possess a single flagellum and form cytoplasmic protrusions up to 2 μ m in length, especially during the

Fig. 6. Electron micrograph of a *Thermodiscus maritimus* cell in division with numerous appendages; platinum-shadowed. Bar = 1 μ m.

stationary phase. The cell envelope consists of an S-layer, probably with sixfold symmetry (Jochimsen et al., 1997). *Stetteria* exhibits a G+C content of the genomic DNA of 65 mol%, which is the highest of all members of the Desulfurococcales (Table 1).

Cells of *Sulfophobococcus* are regular to slightly irregular cocci, 2–5 μ m in diameter. They occur singly or in aggregates and possess a tuft of filaments, whose function remains to be clarified (Hensel et al., 1997). The membrane contains dibiphytanylglycerol tetraethers without pentacyclic rings. As polar head groups, *myo*-inositol phosphate and mono- and diglycosyl units are present. No respiratory lipoquinones were detectable. The G+C content of the genomic DNA is 55 mol% (Table 1).

As indicated by the name, *Thermodiscus* cells are irregular dish to disc-shaped cocci, varying in diameter from about 0.3 to 3 μ m (Fig. 6). The discs are sometimes less than 0.2 μ m thick (Stetter, 1986). Flagella are absent, but pili-like structures, about 10 nm thick and sometimes connecting two cells, are present. The cell envelope is composed of protein subunits, most likely an S-layer, with unknown symmetry (R. Rachel, unpublished observation). The G+C content of the DNA is 49 mol%.

Thermosphaera forms regular cocci of 0.2–0.8 μ m in diameter, which occur singly, in pairs, in short chains, and in grapelike aggregates (Fig. 7a). The aggregates exhibit a weak bluish-green fluorescence at 436 nm. The aggregates are very stable and cannot be disintegrated by enzymatic treatment (e.g., by cellulase, proteinase K or

Fig. 7. Electron micrograph of an aggregate of a) *Thermosphaera aggregans* cells; platinum-shadowed; and b) freeze-etched *Thermosphaera aggregans* cells. Bars are each 1 μm .

trypsin), sonification, or mechanical stirring. The cells possess up to eight flagella. The cell envelope contains a cytoplasmic membrane covered by an amorphous layer of unknown composition about 10–15 nm thick; there is no evidence for a regularly arrayed surface layer protein (Huber et al., 1998; Fig. 7b). Acyclic and cyclic glycerol diphytanyl tetraethers with one to four pentacyclic rings were identified as core lipids. In addition, traces of glycerol diphytanyl diethers are present (Huber et al., 1998). The G+C content of the genomic DNA is 46 mol% (Table 1).

As a characteristic, *Pyrodictium* grows as a three-dimensional network of cells and extracellular hollow tubules (the cannulae; Fig. 8a and b); these cannulae interconnect the cells (Stetter, 1982; König et al., 1988; Rieger et al., 1995). In liquid cultures, the network forms flakes of up to 10 mm in diameter, visible by the naked eye, or, in the case of *P. abyssi*, tiny white balls, about 1 mm in size. The cells are dish- to disc-shaped with diameters between 0.3 and 2.5 μm , frequently exhibiting ultra-flat areas, which are only 0.1–0.2 μm thick (Fig. 8c). The cannulae are about 25 nm in diameter and are composed of glycoprotein subunits in a helical array (Rieger et al., 1995); they often aggregate into large bundles. The genes of three proteins forming the cannulae (*canA*, *canB* and *canC*) have been sequenced (Mai, 1998a). The cannulae are up to 150 μm long and elongate at 1.0–1.5 $\mu\text{m}/\text{min}$ from the proximal end (Horn et al., 1999). As can be visualized under anaerobic conditions at 95°C, using a heatable phase contrast microscope, *Pyrodictium* cells divide by binary fission (Horn et al., 1999). The cell envelope consists of a cytoplasmic membrane, a 35-nm wide periplasmic space (Rachel, 1999), and a “zigzag”-shaped surface-layer protein. The subunits of the surface layer are arranged on a p6 lattice with a center-to-center distance of 21 nm (Dürr et al., 1991; Fig. 8d). Precipitates of zinc and sulfur (most likely zinc sulfide) occur on the cell surface and on the cannulae (Stetter et al., 1983). In addition to the cannulae, flagella with a diameter of about

10 nm are present (Rieger et al., 1995). A heat-inducible molecular chaperone, called the “thermosome,” was found in *Pyrodictium* (Phipps et al., 1993); this chaperone makes up about 80% of all soluble proteins at 108°C (Phipps et al., 1991). In *P. Brockii*, sulfur respiration is proposed to be accomplished by an electron-transport chain composed of a membrane-bound hydrogenase of the nickel-iron-sulfur type, a quinone, a cytochrome *c*, and an unknown sulfur-reducing entity (Pihl and Maier, 1991; Pihl et al., 1992). A protein complex with a molecular mass of 520 kDa was purified from *P. abyssi*; the complex catalyzed the reduction of elemental sulfur to H_2S by molecular hydrogen (Dirmeier et al., 1998). *Pyrodictium abyssi* cells also possess an ATPase complex; the head piece (AF_1) consists of five polypeptides and the AF_0 component of a proteolipid (Dirmeier et al., 2000). The complex is able to restore the formation of ATP in membrane vesicles in vitro. The sulfur-reducing complex and the ATPase are both membrane-bound and are extremely heat stable, exhibiting a temperature optimum of 100°C. *Pyrodictium abyssi* possesses a protein-serine/threonine phosphatase, which is active between 40 and 110°C and has a temperature optimum at 90°C (Mai et al., 1998b). The genomic DNAs of all *Pyrodictium* species exhibit high G+C contents (between 60 and 62 mol%; Table 1).

Cells of *Hyperthermus* are irregular cocci of about 1.5 μm in diameter. They often possess pili-like projections on the cell surface; no network is formed. The S-layer exhibits a hexagonal symmetry with a center-to-center distance of the complexes of 25 nm (Baumeister et al., 1990). The RNA polymerase contains an unsplit B component. The membrane lipids are mainly bis-isopranyl tetraether lipids containing two or more cyclopentane rings. The G+C content of the genomic DNA is 56 mol%.

Pyrolobus cells are regular to irregular lobed cocci, about 0.7–2.5 μm in diameter (Fig. 9a). Like in *Hyperthermus*, no network is formed. In contrast to the other members of the Pyrodicti-

Fig. 8. Electron micrographs of cells of *Pyrodictium abyssi*. a) Stained with uranyl acetate; bar = 2 μm ; b) visualized by scanning electron microscopy; bar = 2 μm ; c) thin section after freeze substitution; bar = 0.2 μm ; and d) freeze-etched; bar = 1 μm .

Fig. 9. Electron micrographs of cells of *Pyrolobus fumarii*: a) thin section; and b) freeze-etched. Bars are 1 μm .

aceae, the cells are covered by an S-layer with p4 (!) symmetry and a center-to-center distance of 19 nm (Blöchl et al., 1997; Fig. 9b). The protein complexes exhibit a central depression, most likely a pore. The periplasmic space is about 45 nm wide. The major core lipids are glycerol dialkylglycerol tetraether and traces of 2,3-di-*O*-phytanlyl-*sn*-glycerol. Crude extracts of *Pyrolobus* cells show a strong crossreaction with antibodies prepared against the thermosome of *Pyrodictium occultum*. Furthermore, a membrane-associated hydrogenase with an optimum reaction temperature of 119°C was found in cells grown on molecular hydrogen and nitrate. The G+C content of the genomic DNA is 53 mol%.

Acidilobus cells are regular to irregular cocci, about 1–2 μm in diameter, which are not flagellated. The cell envelope consists of an S-layer, which is covered by an osmophilic layer (Prokofeva et al., 2000). The G+C content of the genomic DNA is 54 mol%. “*Caldococcus*” cells are 1–3 μm in diameter. Besides the 16S rRNA gene, an isocitrate dehydrogenase, which showed high similarities to bacterial isocitrate dehydro-

genases, was sequenced and expressed (Aoshima et al., 1996b).

Cultivation

Media for Cultivation

Medium for *Desulfurococcus amylolyticus* (Bonch-Osmolovskaya et al., 1988)

NaCl	0.50 g
MgCl ₂ · 6H ₂ O	0.70 g
KH ₂ PO ₄	0.33 g
NH ₄ Cl	0.33 g
CaCl ₂ · 2H ₂ O	0.44 g
KCl	0.33 g
NaHCO ₃	0.80 g
Elemental sulfur	10.0 g
Trace elements (SL 10)	1.0 ml
Trace vitamin solution (see below)	10.0 ml
Yeast extract	0.2 g
Casein hydrolysate	5.0 g
Resazurin	1 mg
Na ₂ S · 9H ₂ O	0.5 g
Distilled water ad	1 liter

Adjust pH to 6.2–6.8 and incubate cultures in a gas phase of N₂/CO₂ (80:20) under pressure (200 kPa).

Trace Element Solution (SL 10)

HCl (25%; 7.7M)	10 ml
FeCl ₂ · 4H ₂ O	1.5 g
ZnCl ₂	70 mg
MnCl ₂ · 4H ₂ O	100 mg
H ₃ BO ₃	6 mg
CoCl ₂ · 6H ₂ O	190 mg
CuCl ₂ · 2H ₂ O	2 mg
NiCl ₂ · 6H ₂ O	24 mg
Na ₂ MoO ₄ · 2H ₂ O	36 mg
Distilled water ad	1 liter

Trace Vitamin Solution (Balch et al., 1979)

B ₆ (pyridoxine) hydrochloride	10 mg
B ₁ (thiamine) hydrochloride	5 mg
B ₂ (riboflavin)	5 mg
Nicotinic (niacin) acid	5 mg
Pantothenic acid (DL Ca-pantothenate)	5 mg
PABA (<i>p</i> -aminobenzoic acid)	5 mg
Lipoic acid	5 mg
Biotin	2 mg
Folic acid	2 mg
B ₁₂ (crystalline)	0.1 mg
Distilled water ad	1 liter

Standard Medium for *Desulfurococcus mucosus*, *D. mobilis* and *D. saccharovorans* (Brock, 1972; Zillig et al., 1982)

(NH ₄) ₂ SO ₄	1.30 g
KH ₂ PO ₄	0.28 g
MgSO ₄ · 7H ₂ O	0.25 g
CaCl ₂ · 2H ₂ O	70 mg
FeCl ₃ · 6H ₂ O	20 mg
MnCl ₂ · 4H ₂ O	18 mg
Na ₂ B ₄ O ₇ · 10H ₂ O	4.5 mg
ZnSO ₄ · 7H ₂ O	0.22 mg
CuCl ₂ · 2H ₂ O	0.05 mg
Na ₂ MoO ₄ · 2H ₂ O	0.03 mg
VOSO ₄ · 2H ₂ O	0.03 mg
CoSO ₄	0.01 mg
Yeast extract (Bacto Difco)	2.0 g
Resazurin	1.0 mg
Elemental sulfur	5.0 g
Na ₂ S · 9H ₂ O	0.5 g
Distilled water ad	1 liter

Adjust pH to 5.5 and incubate cultures in a gas phase of N₂ under pressure (200 kPa).

For culture of *Desulfurococcus saccharovorans*, add per liter 5 g of glucose and reduce the concentration of yeast extract to 0.2 g. Adjust pH to 7.0 and incubate cultures in a gas phase of H₂/CO₂ (80:20) under pressure (200 kPa).

Culture Medium for *Acidilobus aceticus* (Basal Medium)

KCl	330 mg
(NH ₄)Cl	330 mg
KH ₂ PO ₄	330 mg
MgCl ₂ · 6H ₂ O	330 mg
CaCl ₂ · 2H ₂ O	330 mg
Na ₂ S	500 mg
Starch	5.0 g
Yeast extract (Difco)	0.1 g
Resazurin	1 mg
Trace-elements SL-10	1 ml

Trace vitamin solution (Balch et al., 1979)	1 ml
Na ₂ S · 9H ₂ O	700 mg
Distilled water ad	1 liter

Adjust pH to 3.0 with 5M H₂SO₄ and incubate cultures in a gas phase of CO₂.

Culture Medium for *Aeropyrum pernix*

Bacto yeast extract (Difco)	1.0 g
Trypticase peptone (BBL)	1.0 g
Na ₂ S ₂ O ₃ · 5H ₂ O	1.0 g
Synthetic seawater ad	1 liter

Adjust pH to 7.0 and incubate cultures in air. The synthetic seawater known as "JS" consists of Jamarine S synthetic sea salts (Jamarine Laboratory, Osaka, Japan).

Culture Medium for *Pyrodicticum*, *Pyrolobus fumarii*, *Hyperthermus butylicus*, *Ignicoccus*, *Staphylothermus marinus* and *Thermoplasma maritimus* (1/2 SME-medium)

NaCl	13.85 g
MgSO ₄ · 7H ₂ O	3.50 g
MgCl ₂ · 6H ₂ O	2.75 g
KH ₂ PO ₄	0.50 g
NH ₄ Cl	0.50 g
CaCl ₂ · 2H ₂ O	0.38 g
KCl	0.33 g
NaBr	50 mg
H ₃ BO ₃	15 mg
SrCl ₂	7.5 mg
KI	0.05 mg
Trace mineral solution (see below)	10.0 ml
Resazurin	1 mg
Na ₂ S · 9H ₂ O	0.5 g
Distilled water ad	1 liter

This medium is based on the originally described "SME" medium (Stetter et al., 1983), modified by Pley et al. (1991), and described as "1/2 SME-medium" by Blöchl et al. (1997).

For culture of *Pyrodicticum occultum*, add per liter 30 g of elemental sulfur, adjust pH to 5.5, and incubate in a gas phase of H₂/CO₂ (80:20) under pressure (300 kPa).

For culture of *Pyrodicticum brockii*, add per liter 30 g of elemental sulfur and 2 g of yeast extract (Bacto Difco), adjust pH to 5.5, and incubate in a gas phase of H₂/CO₂ (80:20) under pressure (300 kPa).

For culture of *Pyrodicticum abyssi*, add per liter 1 g of yeast extract (Bacto Difco) and 1 g of Na₂S₂O₃, adjust pH to 5.5, and incubate in a gas phase of H₂/CO₂ (80:20) under pressure (300 kPa).

For culture of *Pyrolobus fumarii*, replace NH₄Cl with 1 g/liter of NaNO₃, adjust pH to 5.5, and incubate in a gas phase of H₂/CO₂ (80:20) under pressure (300 kPa).

For culture of *Hyperthermus butylicus*, add per liter 2.5 mg of KI, 6 g of tryptone (Bacto Difco), and 10 g of elemental sulfur, adjust pH to 7.0, and incubate in a gas phase of H₂/CO₂ (80:20) under pressure (200 kPa).

For culture of *Ignicoccus islandicus* and *I. pacificus*, omit trace element solution and add per liter 10 g of elemental sulfur, adjust pH to 5.5, and incubate in a gas phase of H₂/CO₂ (80:20) under pressure (300 kPa).

For culture of *Staphylothermus marinus*, add per liter 1 g of yeast extract (Bacto Difco), 5 g of peptone (Bacto Difco), and 30 g of elemental sulfur, adjust pH to 6.5, and incubate in a gas phase of N₂ under pressure (300 kPa).

For culture of *Staphylothermus hellenicus* and *Stetteria hydrogenophila*, add per liter 1 g of yeast extract (Bacto Difco), 20 g of elemental sulfur, and 20 g of NaCl, adjust pH to 5.5, and incubate in gas phase of H₂/CO₂ (80:20) under pressure (300 kPa).

For culture of *Thermodiscus maritimus*, add per liter 0.2 g of yeast extract (Bacto Difco) and 30 g elemental sulfur, adjust pH to 5.5, and incubate in a gas phase of H₂/CO₂ (80:20) under pressure (300 kPa).

Trace Mineral Solution (modified from Balch et al., 1979)

MgSO ₄ · 7H ₂ O	3.0 g
NaCl	1.0 g
MnSO ₄ · H ₂ O	0.5 g
Ni(NH ₄)(SO ₄) ₂ · 6H ₂ O	280 mg
ZnSO ₄ · 7H ₂ O	180 mg
CoCl ₂ · 6H ₂ O	180 mg
FeSO ₄ · 7H ₂ O	100 mg
CaCl ₂ · 2H ₂ O	100 mg
KAl(SO ₄) ₂ · 12H ₂ O	18 mg
CuSO ₄ · 5H ₂ O	10 mg
H ₃ BO ₃	10 mg
Na ₂ MoO ₄ · 2H ₂ O	10 mg
Na ₂ WO ₄ · 2H ₂ O	10 mg
Na ₂ SeO ₄	10 mg
Distilled water ad	1 liter

The solution is adjusted with H₂SO₄ to pH 1.0.

Culture Medium for *Sulfophobococcus zilligii*

EDTA	25 mg
CaCl ₂ · 2H ₂ O	66 mg
MgCl ₂ · 2H ₂ O	31 mg
KCl	31 mg
FeSO ₄ · 7H ₂ O	51.5 mg
ZnCl ₂	2.1 mg
MnSO ₄	2.3 mg
Na ₄ B ₄ O ₇ · 10H ₂ O	1.8 mg
Glycine	1.5 g
Na ₂ CO ₃	230 mg
Yeast extract	1.0 g
Resazurin	1 mg
Titanium citrate	1–2 mM
Distilled water ad	1 liter

Adjust pH to 7.5 and incubate cultures in a gas phase of N₂/CO₂ (80:20) under pressure (200 kPa).

Culture Medium for *Thermosphaera aggregans* (Huber et al., 1998)

MgCl ₂ · 6H ₂ O	2.2 g
NaHCO ₃	1.0 g
NaCl	0.9 g
KCl	17 mg
(NH ₄)Cl	12.5 mg
CaCl ₂ · 2H ₂ O	7.0 mg
K ₂ HPO ₄ · 3H ₂ O	7.0 mg
Fe(III)Cl ₃	0.05 mg
Trace vitamin solution	
(see above; Balch et al., 1979)	10 ml
Bacto yeast extract (Difco)	1.0 g
Bacto peptone (Difco)	1.0 g
Resazurin	0.02 mg
Na ₂ S · 9H ₂ O	0.5 g
Distilled water ad	1 liter

Adjust pH to 6.5 and incubate cultures in a gas phase of N₂/CO₂ (80:20) under pressure (300 kPa).

Culture Medium for “*Caldococcus noboribetus*” (Aoshima et al., 1996a)

NaCl	0.1 g
CaCl ₂ · 2H ₂ O	0.1 g
FeSO ₄ · 2H ₂ O	0.05 g
Bacto yeast extract (Difco)	0.1 g
Casamino acids	0.1 g
Bacto peptone (Difco)	0.8 g
Trace vitamin solution	
(see above; Balch et al., 1979)	10 ml
Trace mineral solution	
(see below; Aoshima et al., 1996a)	10 ml
Resazurin	1 mg
Elemental sulfur	2.0 g
Na ₂ S · 9H ₂ O	0.5 g
Distilled water ad	1 liter

Adjust pH to 2.7 and incubate cultures in a gas phase of H₂/CO₂ (80:20) under pressure (200 kPa).

Trace Mineral Solution (Aoshima et al., 1996a)

MnSO ₄ · 2H ₂ O	0.5 g
ZnSO ₄ · 7H ₂ O	180 mg
CoSO ₄	180 mg
CuSO ₄ · 5H ₂ O	10 mg
H ₃ BO ₃	10 mg
Na ₂ MoO ₄ · 2H ₂ O	10 mg
Distilled water ad	1 liter

Cultivation in Liquid Media

Aerobic cultivation (for *Aeropyrum pernix*) is carried out in screw-capped tubes (e.g., 180 × 18 mm) containing 10 ml of medium using normal air as gas phase or overpressure (200 kPa). Microaerobic culture medium (for *Pyrolobus fumarii*) does not contain resazurin and sodium sulfide. After solubilization of the salts, the medium is gassed for 45 min with N₂ (1 liter/min), heated to 65°C, evacuated three times, and finally pressurized with N₂ (200 kPa). All anaerobic members of the Desulfurococcales are cultivated using the anaerobic technique of Balch and Wolfe (1976). For small volumes, the organisms are grown in stoppered and pressurized 28-ml serum tubes (borosilicate glass; Schott, Mainz, Germany) or in 120-ml serum bottles (Bormioli, Italy) made of “type III”-glass. One liter of the corresponding medium is flushed with nitrogen or N₂/CO₂ for 20 min in a stoppered glass bottle. Then dissolved oxygen is removed by the addition of 0.5 g of Na₂S·9H₂O, and the pH is adjusted with H₂SO₄ or HCl. The medium is dispensed in an anaerobic chamber and finally the desired gas phase is pressurized by gas exchange at a gas station.

Cultivation on Plates

Growth on solidified media is described for several members of the Desulfurococcales. Colonies of *Pyrolobus fumarii* and *Pyrodictium abyssi* are

obtained on anaerobic media solidified by 0.8% Gelrite (Kelco, San Diego, CA, United States) in the presence of nitrate or thiosulfate as electron acceptor, respectively. The plates are incubated using a stainless steel anaerobic jar (Balch et al., 1979) with an atmosphere of H_2/CO_2 (200 kPa) plus H_2S (5 kPa). After about one week, white colonies (about 1 mm in diameter) will be formed (Pley et al., 1991; Blöchl et al., 1997). For the cultivation of *Hyperthermus*, 0.8% Gelrite plates without electron acceptors are soaked for two min with 5 ml of a saturated solution of S^0 in 1 M $(NH_4)_2S$ and then rinsed with water. Colloidal sulfur precipitates in the surface by acidification with 5–10 ml of 1 M H_2SO_4 for 2 min. After washing with water, the plates are equilibrated overnight with culture medium. The dried plates can be inoculated and incubated as described above. Amber colonies surrounded by clear halos appear in the sulfur layer after 2–3 days (Zillig et al., 1990). *Staphylothermus hellenicus* can be plated on its normal medium, solidified with 1% Phytigel (Sigma) and 2–3% sodium alginate (Roth) according to Kovacs and Rakhely (1996). For growth of *Acidilobus acetatus*, the culture medium (supplemented with 0.05% $MgSO_4$) is solidified by 0.8% Gelrite. Smooth white colonies, about 1 mm in diameter, appear after one week of incubation (Prokofeva et al., 2000).

Preservation

Most Desulfurococcales strains can be stored under anaerobic conditions at 4°C or at room temperatures for several months (or even up to two years). Although not described for all strains, long-term storage is best achieved in culture media containing 5% dimethyl sulfoxide and frozen in the gas phase over liquid nitrogen (around –140°C). No loss of cell viability is usually observed after storage of several years.

Physiology

Within the Desulfurococcales, only hyperthermophilic organisms are known, exhibiting optimal growth temperatures between 85 and 106°C. No representative can grow below 65°C (Table 1). Therefore, the Desulfurococcales is the order that harbors the most thermophilic microorganisms known so far. *Pyrolobus fumarii* exhibits the highest temperature maximum of all life forms on earth, 113°C. It is unable to propagate at a temperature of 90°C or below. Cultures of *Pyrodictium* and *Pyrolobus* species have been shown to survive even autoclaving at 121°C for one hour (Blöchl et al., 1997; Stetter, 1999; Stet-

ter, 2002). In agreement with this, members of the Desulfurococcales have been exclusively enriched and isolated from terrestrial or marine high temperature biotopes. The pH optima of all organisms are neutral to slightly acidic (Table 1). With the exception of *Aeropyrum pernix*, all members of the Desulfurococcales are able to grow under strictly anaerobic culture conditions. In addition, *Pyrolobus fumarii* can alternatively propagate in the presence of low oxygen concentrations.

The metabolic properties of the Desulfurococcales range from strict heterotrophs to obligate chemolithoautotrophs (Table 1). Under autotrophic conditions, molecular hydrogen is used as the electron donor and usually sulfur (or $S_2O_3^{2-}$) is reduced to H_2S (S^0 - H_2 autotrophy, carried out by *Pyrodictium* and *Ignicoccus*). *Ignicoccus islandicus* produces up to 25 μ mol of H_2S per ml of culture medium at the end of the log phase and *Ignicoccus pacificus* is able to convert 10 g of elemental sulfur (dissolved in 1 liter of culture medium) quantitatively to H_2S within two days, although cell propagation stops after about 24 hours (H. Huber, unpublished observation). Besides thiosulfate, *Pyrolobus fumarii* can use nitrate or oxygen as electron acceptor, forming either ammonium or water as the metabolic end product (Blöchl et al., 1997). Also, CO_2 serves as sole carbon source for all autotrophs. *Pyrodictium* contains ribulose 1,5-bisphosphate carboxylase activity, indicating the presence of the Calvin cycle, while no significant activities for the key enzymes of the known three CO_2 -fixation pathways have been detected in *Ignicoccus* (M. Hügler et al., 2003).

Two different forms of respiration are found within the order Desulfurococcales. Sulfur respiration by using various organic substrates occurs within the genera *Desulfurococcus*, *Stetteria* and *Thermoplasma*. Usually complex organic compounds such as beef extract, peptone, yeast extract, casamino acids, carbohydrates or peptides serve as substrates for growth. Additionally, H_2S and CO_2 are formed as end products; in the case of *Stetteria*, acetate and ethanol were also detected. Besides elemental sulfur, this organism can use thiosulfate as an alternative electron acceptor (Jochimsen et al., 1997).

Aerobic respiration of various complex proteinaceous compounds (e.g., yeast extract, peptone and tryptone) is carried out by *Aeropyrum pernix*. Surprisingly, its growth is highly stimulated in the presence of thiosulfate, and no H_2S could be detected, indicating that the organism has a thiosulfate-oxidizing system for energy generation (Sako et al., 1996).

Desulfurococcus, *Staphylothermus*, *Thermoplasma*, *Hyperthermus* and *Sulfophobococcus* grow, depending on the strain, by fermentation

of a broad variety of complex organic compounds like yeast extract, peptides, amino acids, starch, glycogen or pectin. Possible fermentation products include H_2 , CO_2 , acetate, isovalerate, *n*-butanol, propionic acid and phenylacetic acid (Zillig et al., 1982; Zillig et al., 1990; Fiala et al., 1986; Huber et al., 1998). Although the name of the family and order implies the opposite, growth of *Thermosphaera aggregans* and *Sulfo-phobococcus zilligii* is completely inhibited in the presence of elemental sulfur (Hensel et al., 1997; Huber et al., 1998).

The enzymes involved in acetate formation were studied in *Desulfurococcus amylolyticus* and *Hyperthermus butylicus* (Schönheit and Schäfer, 1995). They use, as do all other Archaea, one enzyme: acetyl-CoA synthetase (ADP-forming). In *Desulfurococcus* and *Staphylothermus*, extracellular proteases have been isolated and characterized (Leuschner and Antranikian, 1995).

Genetics

The sequence of the whole genome of *Aeropyrum pernix* was published a few years ago (Kawarabayashi et al., 1999). The genome is 1,670 kb and in total nearly 2,700 open reading frames (ORFs). *Aeropyrum pernix* was the first Crenarchaeote and first aerobic member of the Archaea for which the complete genome sequence has been determined. It is still the only member of the Desulfurococcales whose complete genome is sequenced. In the first publication, more than 50% of the ORFs showed no significant similarity to sequences in databases. One single 16S–23S rRNA operon was identified, while two 5S rRNA genes and 47 tRNA genes were found. Furthermore, fewer “eukaryotic genes” were found than in the sequenced Euryarchaeotes (Faguy and Doolittle, 1999). Sequence comparisons among the assigned ORFs suggested that a considerable number of ORFs were generated by sequence duplication. The sequence data are available on the *Aeropyrum pernix* K1 data base (<http://www.mild.nite.go.jp>).

Ecology

Representatives of the Desulfurococcales thrive in acidic to slightly alkaline biotopes with original temperatures from at least 60°C to more than 100°C. They are typical inhabitants of high-temperature continental solfataric areas and of submarine hydrothermal systems and have been isolated from such biotopes nearly worldwide. They often share these habitats with other thermophilic and hyperthermophilic organisms,

including members of the orders Sulfolobales, Thermoproteales, Thermotogales, and Aquificales. They can be enriched from the anaerobic zone of solfataric soils, which are usually black-colored due to the presence of ferrous sulfide. Depending on the volcanic activity and exhalation of reducing volcanic gases (e.g., H_2S and H_2), this zone starts at a depth of a few centimetres up to about 50 cm below the oxidized layers (Huber et al., 2000b). In marine hydrothermal systems, members of the Desulfurococcales have been found in all depths, from shallow to deep-sea biotopes. Usually they thrive in heated sediments or directly in the chimney walls of “black smokers.”

In their ecosystems, the Desulfurococcales can function as primary producers and/or as consumers of organic material. For primary producers (e.g., *Ignicoccus*, *Pyrodictium* and *Pyrolobus*) elemental sulfur, thiosulfate, nitrate, oxygen and sulfite are suitable electron acceptors for growth, and molecular hydrogen serves as the electron donor. The end product of their metabolism is H_2S , H_2O or ammonium; in addition the organic cell material is formed. The obligate heterotrophs consume organic matter by growth via different types of respiration or fermentation. For anaerobic respiration, sulfur and sulfurous compounds are used as electron acceptors, and H_2S is formed as one metabolic end product besides different organic molecules. Fermentation occurs with several compounds (e.g., proteins), and a great variety of organic acids and alcohols are formed by the different strains, making these Desulfurococcales important members of the carbon cycle in high temperature habitats.

Very recently, a member of the Desulfurococcales (*Ignicoccus* strain KIN4/I) was identified as a symbiotic partner of a representative of a novel phylum of Archaea, “*Nanoarchaeum equitans*” (Huber et al., 2002).

Although several 16S rDNA sequences related to the known Crenarchaeota were obtained from low temperature biotopes, e.g., in freshwater and marine sediments, terrestrial soils, anaerobic digesters, deep subsurface paleosols (for an overview, see Phylogenetic and Ecological Perspectives on Uncultured Crenarchaeota and Korarchaeota in this Volume), none of these organisms had been cultivated so far and nothing is known about their morphology or physiology. In addition, all these environmental sequences are very distantly related to members of the Desulfurococcales.

Biotechnology

In general, heat stable enzymes from hyperthermophiles are of increasing interest for industrial

applications and research. Besides polymer-degrading extracellular enzymes (e.g., amylases, lipases and proteases), metabolic enzymes may serve as potent biocatalysts in technological processes.

Acknowledgments. The authors thank G. Gmeinwieser for technical support, R. Rachel for electron microscopy, and Brian Hedlund for critically reading the manuscript.

The Order Thermococcales

COSTANZO BERTOLDO AND GARABED ANTRANIKIAN

Among the hyperthermophilic archaea, representatives of order Thermococcales form the most numerous group to date. Members of this group are the most frequently isolated hyperthermophiles. They are heterotrophic and as such regarded as the major constituents of organic matter within marine hot water ecosystems (Canganella et al., 1997). They belong to the branch of Euryarchaeota that contains the methanogens, the genus *Thermoplasma*, and the extremely halophilic archaea. The Thermococcales order is actually represented by three genera: *Pyrococcus* (Fiala and Stetter, 1986), *Thermococcus* (Achenbach-Richter et al., 1988) and the newly described *Paleococcus* (Takai et al., 2000). Phylogenetic analysis based on 16 rDNA sequences indicates that the *Paleococcus* strains are members of an ancient lineage of Thermococcales that diverged prior to the formation of the genera *Pyrococcus* and *Thermococcus* (Takai et al., 2000). These three genera include at present 38 species: 2 belonging to the genus *Paleococcus*, 6 belonging to the genus *Pyrococcus*, and 30 to the genus *Thermococcus*. The optimal growth temperature is 95–100°C for members of the genus *Pyrococcus* and 80–90°C for those of the genus *Thermococcus*. *Pyrococcus* strains have been isolated only from marine hydrothermal vents, whereas species belonging to the genus *Thermococcus* have been isolated also from terrestrial fresh water (Ronimus et al., 1997), marine solfataric ecosystems, deep-sea hydrothermal vents (Stetter, 1996) and offshore oil wells (Takahata et al., 2001). Representatives of the order Thermococcales have coccoid cells with or without flagella; they are obligate anaerobic organotrophic thermophiles with a fermentative metabolism using peptides, polysaccharides, or other sugars as carbon sources. Elemental sulfur is either stimulatory or necessary for the growth of these microorganisms. Molecular hydrogen that is produced during fermentation reduces elemental sulfur to H₂S (Schönheit and Schäfer, 1995). Most of Thermococcales are neutrophiles growing optimally at pH 6.0–7.0; only the two species *Thermococcus alkaliphilus* (Keller et al., 1995) and *T. acidam-*

inovorans (Dirmeier et al., 1998) are able to grow optimally at pH 9.0.

Ecology

The Thermococcales are generally found in natural biotopes that are typical for thermophilic microorganisms. They were originally discovered in terrestrial and submarine hot vents and they were then found also in deep subsurface environments. For example, *Thermococcus celer* (Zillig et al., 1983), *T. litoralis* (Britton et al., 1995) and *Pyrococcus* sp. were discovered in an offshore oil production platform in the North Sea (Stetter, 1996), and *T. litoralis* (Neuner et al., 1990) was isolated from a continental oil well (Paris Basin, France). This fact probably indicates the indigenous origin of hyperthermophilic archaea in the deep subsurface biosphere. Another strain, *T. sibiricus*, was isolated from a high temperature oil reservoir in Western Siberia, a location far remote from both the ocean and volcanic areas. The sites where these microorganisms are found can appear to be unusual, but these microorganisms might have been deposited with the original sediment and survived over geologic time by metabolizing buried organic matter (Miroshnichenko et al., 1998; Miroshnichenko et al., 2001).

On the other hand, members of the genus *Pyrococcus* seem to be isolated from only marine environments and belong to a particular ecological niche (Morikawa et al., 1994). As a result of the hydrostatic pressure at deep-sea vents, geothermally heated seawater remains liquid at temperatures up to 400°C (Stetter, 1996; Duffaud et al., 1998). When the hot fluid that is enriched in polymetal sulfides and gasses is mixed with cold (2°C) seawater, minerals precipitate and form so-called “chimneys,” or “smokers” (Fiala and Stetter, 1986). The temperature of the hot fluid that is emitted from the chimney can even reach 300°C (Holden and Baross 1993; Kwak et al., 1995; Gonzalez et al., 1998; Cambon-Bonavita et al., 2003). Members of the genus *Pyrococcus* are common inhabitants of this eco-

logic environment together with other hyperthermophiles belonging to the genera of *Pyrodictium*, *Pyrobaculum*, *Pyrolobus* and *Methanopyrus*. The two strains *Pyrococcus abyssi* and *Paleococcus horikoshii* were isolated from deep-sea vents of the North Fiji Basins, South Pacific Ocean (Erauso et al., 1993), and Okinawa Trough, Japan (Gonzalez et al., 1998), respectively. *Pyrococcus furiosus* and *Pyrococcus woesei* have been discovered along the marine solfataras of the island Vulcano (Italy). The novel barophilic archaeon belonging to the genus *Palaeococcus* was collected from a deep-sea hydrothermal vent chimney at the Myojin Knoll in the Ogasawara-Bonin-Arc, Japan (Takai et al., 2000).

Isolation

For the isolation of hyperthermophilic archaea, complex anaerobic media are usually used which are prepared according to the Hungate technique (Blamey et al., 1999). After taking samples with special syringes, they should be inoculated into serum vials (25–100 ml) or Hungate tubes (10 ml) containing media under an anaerobic atmosphere of CO₂ or N₂. The 1000 ml of medium should also contain 0.2–1% of elemental sulfur and 10–100 µl of resazurin (1 mg/ml) as a redox indicator. Before inoculation, the medium should be reduced with sodium sulfide (Na₂S; 0.05%). The sample may be transported at ambient temperature and kept at 4°C. Most Thermococcales may survive for a long time at cold or ambient temperature. Using special equipment, the samples taken from the deep sea can be transferred to the laboratory under pressure, and enrichment cultures can be prepared under high pressure and temperature. Samples from the deep sea can be collected by employing a manned submersible. In many cases and to increase the cell concentration, marine samples have to be concentrated many fold using a sterilized cross-flow device equipped with a 50-kDa cut-off membrane. For the growth and isolation of marine Thermococcales, the medium MB (Bacto Marine Broth, Difco) can be used and contains, in general, the following components per liter: bacto-peptone, 5 g; bacto-yeast extract, 1 g; Fe(III) citrate, 0.1 g; NaCl, 19.45 g; MgCl₂, 5.9 g; NaSO₄, 3.24 g; CaCl₂, 1.8 g; KCl, 0.55 g; Na₂CO₃, 0.16 g; KBr, 0.08 g; SrCl₂, 34 mg; H₃BO₃, 22 mg; Na-silicate, 4 mg; NaF, 2.4 mg; (NH₄)NO₃, 1.6 mg; and Na₂HPO₄, 8 mg; the final pH is adjusted to 7.6–7.8. If the complete medium from Difco is used, 37.4 g must be added to 1 liter of water. It is important to filter the medium using normal filter paper to prevent the possible precipitation of iron. The medium that is normally

prepared for the cultivation of *Pyrococcus* species is as follows: KH₂PO₄, 0.5 g; NiCl₂ · 6H₂O, 2 mg; trace element solution (Balch et al., 1979), 10 ml; sulfur, 30 g; yeast extract, 1 g; peptone, 5 g; and resazurin, 1 mg. The pH has to be adjusted to 6.4–6.5. After boiling the above-mentioned media under N₂ atmosphere, they should be cooled on ice and transferred under N₂ atmosphere to 10-ml Hungate tubes and sterilized by autoclaving. Before use, the medium must be reduced with a sterile neutral solution of Na₂S · 9H₂O (0.5 g/liter).

To obtain single colonies on plates, the same media can be used including Gelrite (0.8%), and the plates should be stored in anaerobic jars under a N₂ atmosphere at the desirable temperature.

Cultivation

Thermococcales are receiving increasing interest from academia and industry because they provide a unique source of stable biocatalysts and other products such as archaeal lipids and compatible solutes. However, until recently only low cell concentrations (10⁷–10⁸ cells/ml) could be obtained, making application studies very difficult. The main reason for this has to be ascribed to difficulties related to the production and purification of large quantities of biocatalysts and cell components. Special equipment is also needed to cultivate some strains under high pressure and temperature. Innovative bioreactor design to improve biomass yield is required. Because the accumulation of toxic compounds is thought to be responsible for low biomass yields, dialysis fermentation of *Paleococcus woesei* (Blamey et al., 1999) and *P. furiosus* has been performed for effective removal of low-molecular-mass components from the fermentation broth. Unlike many other heterotrophic hyperthermophiles, significant growth of *P. furiosus* is not dependent on the presence of elemental sulfur (S⁰). When dialysis membrane reactors were applied, a dramatic increase in cell yields was achieved (Krahe et al., 1996). The cultivation of the hyperthermophilic archaeon *Pyrococcus furiosus* (growth at 90°C) resulted in cell yields of 2.6 g · liter⁻¹. For *P. furiosus* the optimum stirrer speed was 1,800 rpm, and neither hydrogen nor the metabolic products were found responsible for the comparatively low cell yield. The fermentation processes can be scaled-up from 3 liters to over 30 liters (up to 300 liters). The pilot plant scale offers the possibility of transferring the fermentation performance to a larger industrial scale. In recent experiments it was shown that even the results of the 1-liter dialysis reactor can be reproduced in 30-liter reactors using

Fig. 1. Transmission electron micrographs of a) *Thermococcus aggregans* (from Canganella et al., 1998), b) *Thermococcus siculi* (from Grote et al., 1999), negatively stained with 0.3% phosphotungstic acid.

external dialysis modules. On the other hand, a method was described for growing *P. furiosus* in 600-liter fermentors (Verhagen et al., 2001), which resulted in the production of 500 g of cells (wet weight).

As already mentioned, Thermococcales, isolated from deep sea vents, are able to grow not only at high temperature but also at hydrostatic pressure around 20–30 MPa. Owing to practical difficulties, the growth and the metabolism of barophilic Thermococcales have been poorly investigated. It has been demonstrated that the upper growth temperature is extended at least 3°C when cells of *P. abyssi* are cultivated at 20 MPa. Similar higher thermotolerance and upward shift in the optimal temperature were observed also for *P. endeavori* at 22 MPa (Erauso et al., 1993). More detailed studies with *Thermococcus peptonophilus* (Canganella et al., 1997) and *T. barophilus* (Marteinsson et al., 1999) have also demonstrated that both species are barophilic. In fact, in both cases the growth rate at the optimal growth temperature was higher under in situ hydrostatic pressure than under lower pressure.

Identification and Morphology

In general, in phase contrast microscopy, all known species of Thermococcales appear as spherical cells, mostly as diploid forms constricted to various degrees owing to the duration of the division process throughout the whole generation time. When the cells of Thermococcales are compared to those of Sulfolobales and certain Thermoproteales, the Thermococcales cells are more round, slightly irregular, and their size varies from 0.5 to 2.5 µm. In the final stage of division of Thermococcales cells, the two daughter cells are connected by a thin string of cytoplasm enclosed by a membrane and S-layer. In general, cells show a Gram-negative reaction. Unlike all other strains, *T. aggregans* cells form chains, and cell aggregates are particularly characteristic of this strain. However, the formation of aggregates is not a general characteristic but occurs only after

cultivation of the strain on yeast-tryptone extract (Canganella et al., 1998; Fig. 1a).

Electron microscopy of Thermococcales cells reveals the presence of monopolar polytrichous flagella in most of the species. For example, *P. furiosus* (Fiala and Stetter, 1986), *P. woesei* (Zillig et al., 1987), *P. abyssi* (Erauso et al., 1993), *P. horikoshii* (Gonzalez et al., 1998), *T. acidaminovorans* (Dirmeier et al., 1998), *T. peptonophilus* (Gonzalez et al., 1995) and *T. chitinophagus* (Huber et al., 1996) are all characterized by the presence of a tuft of polar flagella. Nevertheless, this is not a rule. In other strains, the flagella have a fimbriate arrangement as observed for *T. siculi* (Grote et al., 1999; Fig. 1b). In the case of *T. alcaliphilus* (Keller et al., 1995), only a single flagellum is present and in the case of *T. sibiricus*, the flagella are completely absent (Miroshnichenko et al., 2001).

The cytoplasmic membrane (5–10 nm) of *T. chitinophagus* is covered by a bilayered cell envelope with an inner periplasmic space (15–20 nm) and an external, densely stained layer (5 nm), probably corresponding to a surface-layer protein (Huber et al., 1996). The described organization (structure) of the cytoplasmic membrane is more or less similar among the other members of Thermococcales. Thermococcales have the typical archaeal cytoplasmic membrane lipids (ether lipids), and some members also have simple diether lipids (mainly made up of one or two phospholipids) and trace amounts of tetraethers. The presence of two rare acyclic and cyclic glycerol diphytanyl tetraethers has been reported in *T. chitinophagus* (Huber et al., 1996). However, more detailed studies have been carried out on the lipid structure of *T. hydrothermalis* isolated from a deep-sea hydrothermal vent. On the basis of acid methanolysis and spectroscopic studies, the polar lipids (amounting to 4.5% [w/w] of the dry cells) included diphytanyl glycerol diethers and dibiphytanyldiglycerol tetraethers in a 45 : 55 ratio. No cyclopentane ring was present in the tetraethers. From the neutral lipids (0.4% [w/w] of the dry cells), four di- and tri-unsaturated acyclic tetraterpenoid hydrocarbons and low amounts of di- and tetraethers

(occurring in free form) were identified. All are structurally related to lycopane. The presence of these hydrocarbons provides some evidence that lycopane, widely distributed in oceans, could be derived, at least partially, from the hydrocarbons synthesized by some hyperthermophilic archaea. Analysis of the uninoculated culture medium indicates that fatty acid derivatives and some steroid and triterpenoid compounds identified in the lipidic extract of the archaea probably originate from the culture medium (Lattuat et al., 1998).

Physiology and Metabolism

Most of Thermococcales species are obligate anaerobic organotrophic thermophiles that prefer to utilize polymeric substrates like proteins and carbohydrates (preferentially oligo- and polysaccharides) as carbon and energy sources. Elemental sulfur is required in some cases for the growth and is used as an electron acceptor to remove reducing equivalents that are produced during fermentation. However, these physiological characteristics are not the rule for all members of the order Thermococcales and some differences can be observed in the three genera *Thermococcus*, *Pyrococcus* and *Paleococcus* (Selig et al., 1997; Table 1).

Species of the genus *Pyrococcus* are heterotrophic and sulfur-reducing microorganisms. Growth is observed when complex organic substrates such as yeast extract, peptone, tryptone, meat extract, and peptides are used (Fiala and Stetter, 1986). *Pyrococcus furiosus* and *P. woesei* can also grow on various carbohydrates such as starch (Biller et al., 2002), glycogen, pullulan (Blumentals et al., 1990; Costantino et al., 1990), cellobiose and pyruvate (Kengen et al., 1993). *Pyrococcus glycovorans* grows on proteinaceous substrate and different carbohydrates and, in addition, it is able to use glucose as carbon source, a feature that appears to be unique in hyperthermophiles (Barbier et al., 1999). *Pyrococcus abyssi* and *P. horikoshii* are unable to grow on carbohydrates (Erauso et al., 1993; Gonzalez et al., 1998). Unlike the results reported in the literature, in many cases some members of Thermococcales can even grow on modified media in the absence of sulfur. Members belonging to the genus *Thermococcus* appear to grow mainly on media containing complex proteinaceous substrates such as yeast extract or tryptone as the sole carbon and energy source. Some species like *Thermococcus peptonophilus*, *T. alcaliphilus* and *T. zilligii* are unable to grow on amino acid mixtures (Gonzalez et al., 1995; Keller et al., 1995). There are few reports on the successful cultivation of hyper-

thermophiles on defined minimal media. A minimal defined medium has been reported for the cultivation of *Thermococcus acidaminovorans*, which uses defined amino acids as the sole energy source (Dirmeier et al., 1998). *Thermococcus aggregans* and *T. aegaeicus* strains instead are able to use carbohydrates as substrates. *Thermococcus aggregans* is able to grow on starch and maltose and *T. aegaeicus* also utilizes starch but under a N₂/CO₂ atmosphere (Canganella, et al., 1998). Significant growth on maltose and slow growth on cellobiose were observed for *T. hydrothermalis* (Godfroy et al., 1997; Gruyer et al., 2002) and *T. fumicolans* (Godfroy et al., 1996). Interestingly, *T. chitinophagus* represents the only species able to grow on chitin as a carbon source (Huber et al., 1996). With the exception of *T. stetteri* (Miroshnichenko et al., 1989), *T. profundus* (Kobayashi et al., 1994; Kwak et al., 1995) and *T. waiotapuensis* (Gonzalez et al., 1999), *Thermococcus* strains are stimulated by addition of sulfur, but sulfur is not absolutely required (Arab et al., 2000). The recently identified archaeon *Palaeococcus* sp. possesses most of the morphological and physiological properties typical of Thermococcales. It, however, displays an absolute requirement for either elemental sulfur or ferrous iron (Fe²⁺). The requirement for iron represents an ancient characteristic of early microbial metabolism, in light of geochemical data suggesting the properties of habitats occupied by microorganisms belonging to the order Thermococcales (Takai et al., 2000).

The generation time of the members of Thermococcales is the shortest among Archaea. The time range is between 25 min for *T. peptonophilus* and 70 min for *T. stetteri*. The doubling time of the strains belonging to the members of the genus *Pyrococcus* is around 30–35 min (Table 1).

Sugar and Peptide Degradation Pathways

As already described, many Thermococcales show heterotrophic growth on a variety of carbohydrates. This suggests that oligosaccharides with varying degrees of polymerization are transported into the cell and are subsequently hydrolyzed to glucose. Various studies have focused both on the transport of the saccharides into the cell and on the pathways that are used to degrade the glucose (Schönheit and Schäfer, 1995). For *Thermococcus litoralis*, a transport system for both maltose and trehalose has been described that probably represents an ATP-binding cassette (ABC) transporter (Horlacher et al., 1998; Xavier et al., 1999). The trehalose-maltose binding protein, TMBP, and the ATPase subunit, MalK, have been functionally expressed in *Escherichia coli* (Greller et al., 1999; Greller et al., 2001; Diederichs et al., 2000). These binding

*Complex substrates: yeast extract, tryptone, peptone.

protein-dependent transport systems exhibit an unusually high affinity for the sugar, with a K_m in the submicromolar range. While glycolysis in thermophilic bacteria proceeds in a conventional way, glucose catabolism by Thermococcales (as well as in other hyperthermophilic archaea) differs from the canonical pathways, involves novel enzymes, and shows unique control. In an effort to understand the metabolism of cellobiose in *P. furiosus*, a binding protein-dependent ABC transport system for oligosaccharides was discovered. The 70-kDa protein is responsible for the uptake of cellobiose and most other α -glucosides (Koning et al., 2001).

Two major pathways are known to be involved in the degradation of glucose in prokaryotes: the Embden-Meyerhof (EM) and the Entner-Doudoroff (ED) pathways. In general, they differ in the key enzyme acting on glucose or glucose-6-phosphate and in the subsequent aldolytic cleavage of the intermediates fructose-1,6 biphosphate (EM) and 2-keto-3-deoxy-6-phosphogluconate (ED). So far, sugar degradation has been analyzed in representative species of the genera *Thermococcus* and *Pyrococcus*. The analysis included 1) determination of ^{13}C -labeling patterns by ^1H - and ^{13}C -NMR spectroscopy of fermentation products derived from pyruvate after fermentation of specifically ^{13}C -labeled glucose by cell suspensions, 2) identification of intermediates of sugar degradation after conversion of ^{14}C -labeled glucose by cell extracts, and 3) measurements of enzyme activities in cell extracts (Schönheit and Schäfer, 1995; De Vos et al., 1998). It has been established that in the three Thermococcales, *P. furiosus*, *T. celer* and *T. litoralis*, glycolysis appears to occur via a modified EM pathway. This pathway is unusual because the hexose kinase and phosphofructokinase steps are dependent on ADP rather than ATP, and a novel tungsten-containing enzyme termed "glyceraldehyde-3-phosphate:ferredoxin oxidoreductase" (GAPOR) replaces the expected glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and phosphoglycerate kinase. In contrast, other thermophilic Archaea (like *Sulfolobus solfataricus* and *Thermoplasma acidophilum*) degrade glucose via the ED pathway, and hyperthermophilic bacteria belonging to the order Thermotogales degrade glucose via conventional forms of the EM and ED pathways (Schönheit and Schäfer, 1995; De Vos et al., 1998). A final step in sugar fermentation is the conversion of acetyl-CoA into acetate that produces ATP. Also in this crucial step, the Thermococcales are unique because they have a single enzyme, an ADP-dependent acetyl-CoA synthase, while in bacteria this reaction is catalyzed by two different enzymes, phosphate acetyltransferase and acetate kinase (Fig. 2). In addition, *P.*

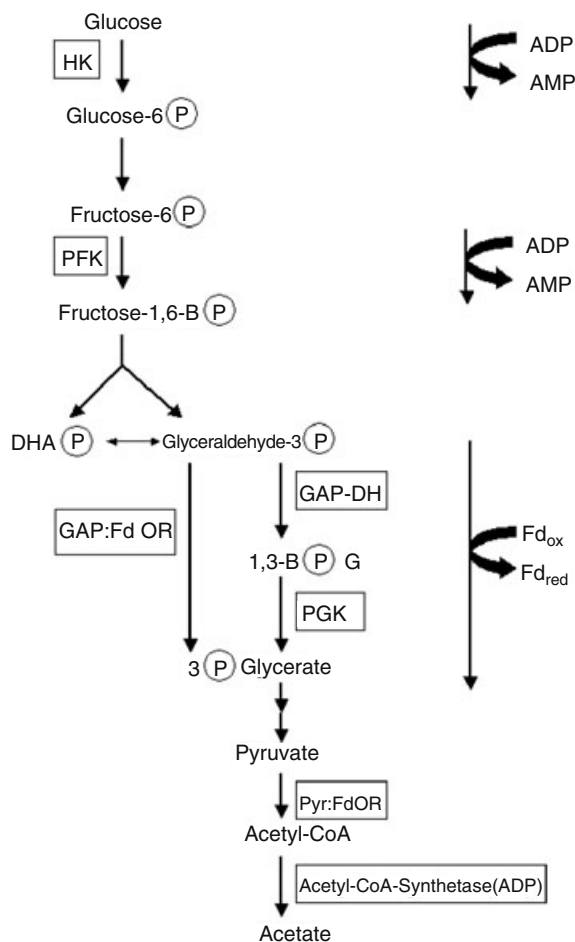

Fig. 2. Embden-Meyerhof-type glycolytic pathway in the genera *Pyrococcus* and *Thermococcus*. The phosphoryl-donor specificities (ADP-AMP) of hexokinase (HK) and 6-phosphofructokinase (PFK) and the enzyme proposed for glyceraldehyde-3-phosphate oxidation are indicated (GAP:FdOR, glyceraldehyde-3-phosphate:ferredoxin oxidoreductase; GAP-DH, glyceraldehyde-3-phosphate dehydrogenase; PGK, phosphoglycerate kinase; DHA-P, dihydroxyacetonephosphate; 1,3-BPG, 1,3-bisphosphoglycerate; Fd_{ox}, oxidized ferredoxin; Fd_{red}, reduced ferredoxin; and Pyr:FdOR, pyruvate:ferredoxin oxidoreductase).

furiosus has the capacity to convert pyruvate into alanine, which acts as an alternative electron sink. This reaction involves the combined activity of both alanine aminotransferase and glutamate dehydrogenase (Kengen et al., 1994).

The operation of a new glycolytic pathway was demonstrated in nongrowing cells of *Thermococcus zilligii* by isotopic enrichment analysis of the end products derived from fermentation of ^{13}C -labeled glucose. The new pathway involves the formation of formate, derived from C-1 in glucose, via cleavage of a six-carbon carboxylic acid. The operation of a novel glycolytic strategy in *T. zilligii* with two branches diverging at the level of glucose-6-phosphate was demonstrated (Ron-

imus et al., 2001). Glucose is phosphorylated by an ADP-dependent hexokinase to glucose-6-phosphate, which is subsequently degraded by two glycolytic branches: an EM-type glycolytic pathway and a new route where formate is produced by a reaction involving cleavage of the C-1 carboxylic group of a six-carbon compound to yield formate and a pentose phosphate. By analogy with the pyruvate-formate-lyase reaction, it was suggested that the six-carbon compound is a β -ketoacid, such as 2-keto-3-deoxy-6-phosphogluconate, derived from 6-phosphogluconate. The contribution of the novel glycolytic branch was twice as high as that of the EM-type pathway when cells were grown on tryptone, and the inverse relationship was found for cells grown in the presence of glucose. This is the first report of a glycolytic pathway involving the formation of formate from C-1 in glucose. It is noteworthy that the most atypical member of the Thermococcales, *T. zilligii*, possesses also this unusual glycolytic feature (Ronimus et al., 1999; Ronimus et al., 2001).

The pathways of peptide metabolism have been well studied in *P. furiosus*. Amino acid catabolism in *P. furiosus* is thought to involve four distinct 2-keto acid oxidoreductases that convert transaminated amino acids into their corresponding coenzyme A (CoA) derivatives (Blamey and Adams, 1993; Mai and Adams, 1994; Mai and Adams, 1996; Heider et al., 1996). These CoA derivatives, together with acetyl-CoA produced from glycolysis via pyruvate, are then transformed to their corresponding organic acids by two acetyl-CoA synthetases unique to archaea, with concomitant substrate-level phosphorylation to form ATP. Alternatively, it has been postulated that depending on the redox balance of the cell, 2-keto acids are decarboxylated to aldehydes and then oxidized to form carboxylic acids by a second tungsten-containing enzyme, aldehyde:ferredoxin oxidoreductase (AOR; Mai and Adams, 1996). A third enzyme of this type, termed "formaldehyde:ferredoxin oxidoreductase" (FOR), is thought to be involved in the catabolism of basic amino acids (Roy et al., 1999; Adams et al., 2001).

Molecular Biology

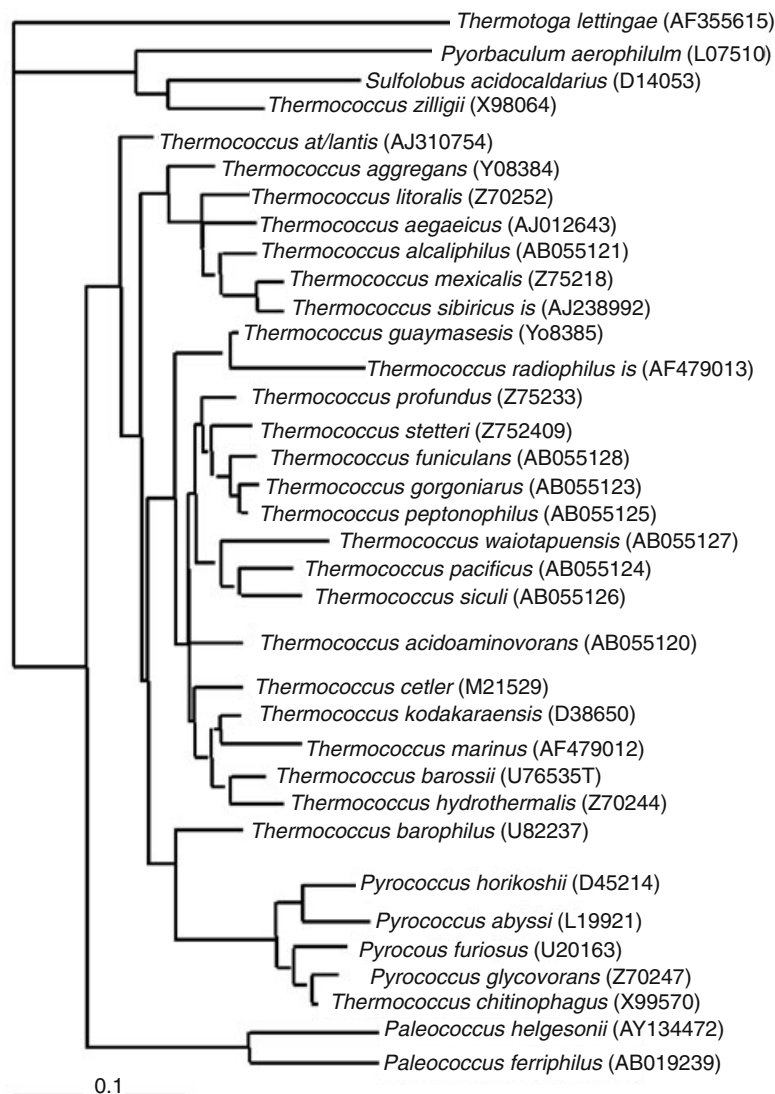

The DNA G+C content of members of Thermococcales varies from 37.5 mol% for *Pyrococcus woesei* to 60 mol% for *Thermococcus barossii*. The abyssal strains *P. abyssi*, *P. horikoshii* and *P. glycovorans* are characterized by a higher G+C (44–47 mol%) content than that of the coastal strains *P. furiosus* and *P. woesei* (38 mol%). A G+C content higher than 40 mol% is a typical feature of most *Thermococcus* species, but also in this genus, a distinction can be made. According

to Godfroy et al. (1997), the strains of the genus *Thermococcus* can be divided on the basis of their G+C contents into the following two groups: 1) a group of strains with high G+C content (50–58 mol%), including the strains from shallow marine environment, *T. celer* and *T. stetteri*, and three deep-sea species *T. profundus*, *T. peptinophilus* and *T. funiculans*; and 2) a group of strains with low G+C content (38–47 mol%), including deep-sea strains of *T. chitinophagus*, *T. alcaliphilus* and *T. barophilus*, an organism from a shallow marine environment, *T. litoralis*, and the microorganism from a terrestrial high temperature oil reservoir, *Thermococcus sibiricus* (Table 1).

Phylogenetic studies based on 16S rDNA analysis reveal that *Pyrococcus* and *Palaeococcus* strains are clustered separately from *Thermococcus* species. However, the topology of the dendrogram based on neighbor-joining algorithms clusters the *Thermococcus* species in a different number of branches, thus indicating that at the phylogenetic level, diversity in the same genus within high temperature environments is remarkable (Fig. 3).

The recent advances in genome projects have provided a considerable amount of data, which enables genomes of distant organisms to be compared in a comprehensive and integrative way. Comparisons of closely related species constitute a complementary approach crucial to the understanding of genome evolution. At the genomic level, these comparisons provide a unique opportunity to understand the mechanisms that determine chromosomal organization and evolution. At the proteomic level, this powerful strategy can be used to assess the genuine extent of gene losses and gains that lead to the observed divergence of coding capacity. Comparison of the genomes of Thermococcales has been already performed on three closely related species: *Pyrococcus abyssi* (Cohen et al., 2003; Genoscope website <http://www.genoscope.cns.fr>), *Pyrococcus horikoshii* (Kawarabayasi et al., 1998; Kawarabayasi et al., 2001; The National Institute of Technology and Evaluation (NITE) website <http://www.bio.nite.go.jp>) and *Pyrococcus furiosus* (Maeder et al., 1999; Lecompte et al., 2001; Environmental Genome Project sponsored by the National Institute of Environmental Health Sciences <http://www.genome.utah.edu>; ORNL website <http://www.ornl.gov>). Several genome features of *P. abyssi*, *P. horikoshii* and *P. furiosus* affirm the close relationship among the three species, including similar G+C content and RNA elements, like rRNA and tRNA. At the genomic level, the comparison reveals that a differential conservation among four regions of the *Pyrococcus* chromosomes correlates with the location of genetic elements mediating DNA reorganization. At the proteomic level, the closer proximity of

Fig. 3. Phylogenetic tree of the order Thermococcales as derived from neighbor-joining analysis of 16S rRNA. The tree was constructed by maximum-likelihood analysis using the program CLUSTAL W (Higgins et al., 1996). The 16S rRNA gene sequences were all obtained from GenBank. The accession number of the sequences is indicated within the brackets. Bar indicates one substitution per 100 nucleotides.

P. abyssi and *P. horikoshii* is affirmed by their average amino acid identity (77%) and their chromosomal organization. Nevertheless, the evolutionary distance between *P. abyssi* and *P. horikoshii* is not negligible relative to *P. furiosus* because the average amino acid identities are also high between *P. furiosus* and the two other species (72% with *P. abyssi* and 73% with *P. horikoshii*). The comparison of the three *Pyrococcus* species sheds light on specific selection pressure acting both on their coding capacities and on their evolutionary rates. The two independent methods, the “reciprocal best hits” approach and a new distance-ratio analysis, allow detection of the false orthology relationships within the *Pyrococcus* lineage. Such analyses reveal a high amount of differential gains and losses of genes since the three closely related species diverged. The resulting polymorphism is probably linked to an adaptation of these free-living organisms to differential environmental constraints.

Enzymology

Because members of Thermococcales grow at high temperature, their enzymes are highly thermostable and thermophilic. A large number of enzymes show no significant loss of activity after several hours at 100°C and are even active at temperatures that exceed the optimal growth temperature of the organism from which they were isolated (Bertoldo and Antranikian, 2002). These properties make hyperthermophiles very attractive for new biotechnological applications. To date, a large number of extracellular and intracellular enzymes have been characterized. They include the extracellular enzymes like amylases, pullulanases, α -glucosidases and proteases but also intracellular enzymes like dehydrogenases, oxidoreductases and DNA polymerases (Table 2). Interestingly, the ability of hyperthermophiles to produce cellulases, xylanases and pectinases seems to be very limited,

Table 2. Properties of enzymes from Thermococcales with potential biotechnological implications.

Symbol: –, not determined.

^aValues in parentheses give the optimal growth temperature for each organism in °C.

and only in few cases the formation of cellobiohydrolase has been reported. Among the intracellular enzymes, the DNA polymerase and DNA ligase from *Pyrococcus* sp. (Southworth et al., 1996) and the DNA polymerase from *Thermococcus* strains especially have attracted further interest because of their potential in commercial applications to PCR. For reviews on the enzymology of hyperthermophilic archaea and their potential applications refer to the following articles (Sunna et al., 1997; Niehaus et al., 1999; Lévêque et al., 2000; Bertoldo and Antranikian, 2002; Bohlke et al., 2002).

The Genus *Archaeoglobus*

PATRICIA HARTZELL AND DAVID W. REED

Archeal Sulfate Reducers

The domain Archaea contains two genera, thermophilic *Archaeoglobus* and thermoacidophilic *Caldivirga*, which obtain energy by reducing oxidized sulfur compounds to H₂S under anaerobic conditions. Both *Archaeoglobus fulgidus* and *Caldivirga maquilingensis* thrive at 85°C, the optimal temperature for growth (Itoh et al., 1999).

Phylogeny

The genus *Archaeoglobus* is classified in the Archaeoglobaceae family, Archaeoglobales order, Archaeoglobi class, Euryarchaeota phylum, of the domain Archaea (Huber and Stetter, 2001). *Archaeoglobus* is a chemolithoautotrophic or chemoorganotrophic microorganism using sulfate, sulfite or thiosulfate as electron acceptor, with the formation of hydrogen sulfide as the end product.

Habitat

Dissimilatory sulfate-reducers inhabit aquatic and terrestrial sediments and play an essential role in the biogeochemical sulfur cycle. Although oxygen is the most abundant terrestrial element on earth and more electronegative than sulfur, sulfate (an oxidized form of sulfur) is a major anion in anoxic environments in which sulfur predominates (such as seawater) and serves as the electron acceptor for many organisms including *Archaeoglobus*. Sulfate can be reduced by sulfate-reducers to hydrogen sulfide (H₂S), which can be assimilated by other organisms as a substrate for growth.

The *Archaeoglobus* genus contains, to date, four cultured species, *A. fulgidus*, *A. profundus*, *A. veneficus* and *A. lithotrophicus*. The type strain *A. fulgidus* VC-16, the first *Archaeoglobus* species identified, is a chemolithoautotroph that grows preferentially as a chemoorganotroph. It was isolated initially from near anoxic shallow and abyssal submarine hydrothermal vents off

the coast of Italy (Stetter et al., 1987) and later from hot oil field waters in the North Sea (Beeder et al., 1994). In addition to *Archaeoglobus fulgidus* strain VC-16, strains 7324 and Z have been partially characterized.

The chemolithoheterotroph *A. profundus* obligately requires H₂ as an electron donor (Burggraf et al., 1990). *Archaeoglobus profundus* lacks the carbon monoxide dehydrogenase necessary for CO₂ fixation into acetyl-CoA and hence is unable to grow autotrophically (Vorholt et al., 1995). Like *A. fulgidus*, *A. profundus* also was isolated from a marine hydrothermal system. *Archaeoglobus fulgidus* strain Z was isolated from Vulcano (Zellner et al., 1989) and strain 7324 from hot oil field waters off the coast of Norway (Beeder et al., 1994). *Archaeoglobus fulgidus* and related species, such as *A. veneficus*, have been identified in mid-Atlantic ridge hydrothermal vents (Reysenbach et al., 2000) and in association with methanogens in the petroleum hydrocarbon-rich Guaymas Basin off the coast of Mexico (Teske et al., 2002). *Archaeoglobus veneficus*, a black smoker isolate, does not use sulfate as an electron acceptor but can convert sulfite into sulfide (Huber et al., 1997). It is the fastest growing species of the genus *Archaeoglobus* with a doubling time of one hour. *Archaeoglobus lithotrophicus* was isolated from fluids in a North Sea oil field and is an obligate chemolithoautotroph with a doubling time of about two hours (Stetter et al., 1993; Vorholt et al., 1995). *Archaeoglobus lithotrophicus* grows on H₂ : CO₂ (80 : 20 ratio) and sulfate, but has lower levels of F₄₂₀ (a coenzyme and a 7,8-didemethyl-8-hydroxy-5-deazariboflavin derivative) and lower activities of F₄₂₀-dependent dehydrogenases than strain VC-16 has. *Archaeoglobus fulgidus* has also been identified in terrestrial environments including hot springs in Yellowstone National Park (Barns et al., 1994) and terrestrial oil wells (P. Hartzell, unpublished results) where sulfate is an important component. Because sulfate reducers have a high affinity for hydrogen gas, the capacity for sulfate reduction likely allows *A. fulgidus* to compete favorably against hydrogenotrophic methanogens in

Table 1. Characteristics of species from the genus *Archaeoglobus*.

sulfate-rich environments. Although *A. fulgidus* is the focus of this chapter, a summary of the characterization of the other species is included in Table 1.

Archaeoglobus fulgidus

Archaeoglobus fulgidus strain VC-16 is the most extensively characterized member of the genus *Archaeoglobus*. The genome for this strain (DSM4304) has been sequenced at The Institute for Genome Research, *Archaeoglobus fulgidus* DSM4304 Genome page). Initially *A. fulgidus* was shown to be in the euryarchaeotal branch between the Methanococcales and Thermococcales on the basis of 16S rRNA sequencing (Achenbach-Richter et al., 1987). However, reevaluation of this phylogenetic position showed that *Archaeoglobus* branches between the Methanobacteriales and Methanomicrobiales—extreme halophiles (Woese et al., 1991). Our analysis positions the *Archaeoglobus* genus branching most closely with the *Methanococcales* (e.g., *Methanocaldococcus*), between the *Thermococcales*/*Methanopyrales* and *Methanobacteriales* (e.g., *Methanothermobacter*), Euryarchaeota, as shown in Fig. 1.

The 16S rRNA link between *Archaeoglobus* and methanogens is supported by biochemical data. *Archaeoglobus fulgidus* fluoresces at 420 nm because, like the methanogens, it contains the deazaflavin cofactor F₄₂₀ (Gorris et al., 1991). *Archaeoglobus fulgidus* expresses activity for each of the enzymes and cofactors associated with methanogenesis, but it lacks the components such as 2-mercaptoethane sulfonic acid coenzyme M and the nickel tetrapyrrole cofactor F₄₃₀ that are required for the terminal step in

methane (CH₄) production (Möller-Zinkhan et al., 1989). Genes encoding the methyl-CoM reductase are absent. In *Archaeoglobus*, the methanogenic cofactors are used in the reverse direction during the oxidation of lactate.

Identification

The name *Archaeoglobus* means “ancient spheres.” As shown in Figs. 2 and 3, *A. fulgidus* cells are 0.4–1.2 μm wide, with a triangular, dimpled-shaped morphology (Stetter, 1988). *Archaeoglobus fulgidus* cells are polytrichously flagellated at one end (Zellner et al., 1989). The three dimensional structure of *A. fulgidus* is dome-shaped, similar to the structure of *Halo-bacterium volcanii* and *Sulfolobus solfataricus*. Like other archaea, *A. fulgidus* lacks a peptidoglycan layer; however, the envelope consists of a single layer (S-layer) of hexagonally arranged monomeric peptide units (Kessel et al., 1990). Some of the units are symmetric while others deviate considerably from symmetry. Unlike for *H. volcanii* and *S. solfataricus*, there is no evidence of protein-protein interconnectivity in the hexameric complexes. The S-layer is in close contact with the membrane, providing a narrow periplasmic space and some structural support. Indeed partial removal of the membrane-supporting base weakens the surface layer, making it susceptible to shearing forces.

Archaeoglobus fulgidus membrane has phytanyl ether-linked lipids which are arranged as a bilayer rather than a more stable monolayer membrane found in many hyperthermophiles (Kessel et al., 1990). This is surprising considering that *A. fulgidus* cells grow optimally at 83°C, above the classification for hyperthermophiles (>80°C). *Archaeoglobus fulgidus* produces a

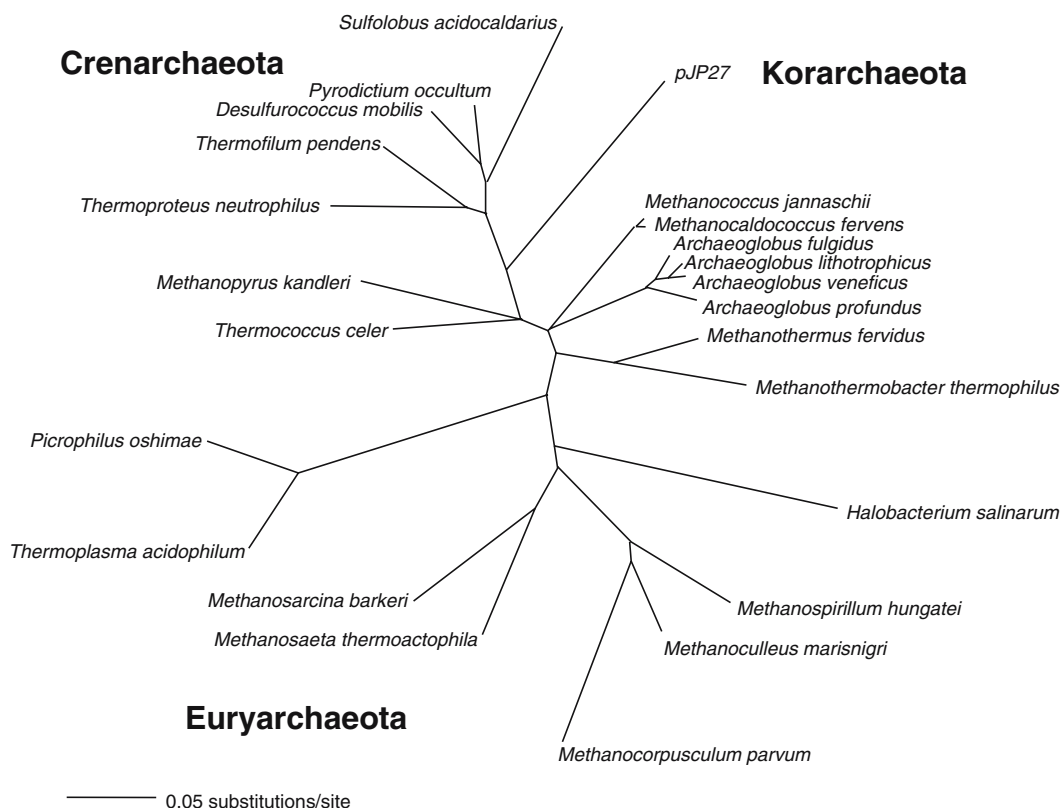

Fig. 1. *Archaeoglobus fulgidus* groups near a subset of methanogens in the Euryarchaeota. Phylogenetic relationships of archaeal 16S rRNA sequences as determined by Jukes-Cantor distance analysis. The scale bar represents the average number of nucleotide substitutions per site. Alignments were performed with known taxonomic sequences obtained from the Ribosomal Database Project II (Maidak et al., 2000) and GenBank (Benson et al., 2000; Wheeler et al., 2000) databases using the BioEdit Sequence Alignment Editor freeware (version 5.0.9; Department of Microbiology, North Carolina State University, Raleigh, NC). Sequences were manually corrected using the MacClade software package (version 3.0; Sinauer Associates, Inc., Sunderland, MA) to ensure only homologous nucleotides were compared between sequences. The edited alignments were evaluated with maximum parsimony, maximum likelihood and distance methods using the PAUP package (version 4.0b10; Sinauer Associates, Inc., Sunderland, MA). Phylogenetic inference and evolutionary distance calculations were generated using the Jukes-Cantor distance model (gamma parameter = 2.0). Nucleotide sequence accession numbers are provided: *Archaeoglobus fulgidus*, *Archaeoglobus lithotrophicus*, *Archaeoglobus profundus*, *Archaeoglobus veneficus*, *Desulfurococcus mobilis*, *Halobacterium salinarum*, *Methanocaldococcus jannaschii*, *Methanocorpusculum parvum*, *Methanoculleus marisnigri*, *Methanopyrus kandleri*, *Methanosaeta thermoacetophila*, *Methanosarcina barkeri*, *Methanospirillum hungatei*, *Methanothermobacter thermophilus*, *Methanothermus fervidus*, pJP27, *Picrophilus oshimae*, *Pyrodictium occultum*, *Sulfolobus acidocaldarius*, *Thermococcus celer*, *Thermophilum pendens*, *Thermoplasma acidophilum*, and *Thermoproteus neutrophilus*.

Fig. 2. *Archaeoglobus fulgidus* cells. Cells of *A. fulgidus* are typically irregular in shape, having a triangular or dimpled appearance. A: Bar = 2 μ m. B: Bar = 0.5 μ m. Photos were taken with a Nikon FXA equipped with diffraction interference contrast.

Fig. 3. Thin sections of *A. fulgidus* cells. Cells were embedded in LR White and examined using a JEOL transmission electron microscope at an acceleration magnification of 80 kV (Pagala et al., 2002). Bar = 0.5 μ m.

3-hydroxy-3-methylglutaryl CoA (HMG-CoA) reductase (AF1736), an important intermediate for synthesis of cholesterol and lipids, suggesting that these membrane components are produced via mevalonate (Kim et al., 2000).

Isolation

Archaeoglobus fulgidus can be selectively enriched and maintained under anaerobic conditions in sulfate-thiosulfate-lactate (STL, described below) medium at 83°C (Stetter et al., 1987; Hartzell et al., 1999). Lactate can be used as the sole electron and carbon source for *A. fulgidus*. *Archaeoglobus profundus* can be enriched with medium containing acetate and H_2 : CO_2 (80:20) (Burggraf et al., 1990). Solutions are made anoxic by boiling media and sparging with oxygen-free N_2 gas prior to adding to serum vials. Vials are stoppered, sealed with aluminum crimps and autoclaved. The medium is reduced with 0.5 mM sodium sulfide (Na_2S)

and 1 mM sodium thiosulfate ($Na_2S_2O_3$) prior to inoculation.

Pure isolates can be obtained by serially diluting cells into solid medium under anaerobic conditions. A 0.5-ml aliquot from each dilution is mixed with 5 ml of sulfate-thiosulfate-lactate (STL) medium in melted Gelrite (2%), added to anaerobic tubes, stoppered and spun over an ice bath using a tube roller which produces a thin layer of agar in the tube (Rodabough et al., 1995). Tubes are incubated upright at 83°C, where colonies form in the roll tube agar and are easily seen after about 7–10 days because cells produce H_2S , which forms a black FeS precipitate in the colonies (Fig. 4, Panel B).

For large-scale growth, 40-liter glass carboys can be used (Hartzell et al., 1999; Fig. 4, Panel A). A glass (or enamel-protected) fermentor is used instead of stainless steel because the production of H_2S during growth would cause pitting (from surface oxidation) of metal fermentors. Tris-maleate (20 mM at pH 6.1) can replace 1,4-piperazine bis-(2-ethanesulfonic acid) PIPES in large-scale growth. Higher cell densities are obtained if temperature is maintained at 74–80°C, rather than 83°C, and pH is maintained near 7.2–7.8 (Reed and Hartzell, 1999). The lag period for growth in a carboy is typically 15–20 hours. Typically a 3.6-hour doubling time results in a final cell density of about $5\text{--}6 \times 10^8$ cells/ml (0.8 g/liter wet weight).

Cultivation

The *A. fulgidus* sulfate-thiosulfate-lactate (STL) base growth medium contains (per liter) 100 ml of 10X salt solution, 20 ml of 1 M PIPES (piperazine- N,N' -bis[2-ethanesulfonic acid]) buffer at pH 7.0, 1 ml of 1000X trace element stock solution, 1 ml of 0.2% $(NH_4)_2Fe(SO_4) \cdot 2H_2O$, 0.5 g of yeast extract, and 7 ml of 30% sodium lactate (Balch et al., 1979). The pH of the base medium is adjusted to 6.7 with 1 M NaOH or KOH.

The 10X salt solution (1 liter) is prepared using the following three solutions, dissolved separately prior to combining. Solution I contains 74 g of $MgSO_4$, 3.4 g of KCl, 27.5 g of $MgCl_2 \cdot 6H_2O$, 2.5 g of NH_4Cl , 178 g of NaCl and 5 ml of 0.2% resazurin (the redox indicator) dissolved in 800 ml of nanopure (np) H_2O . Solution II contains 1.4 g of $CaCl_2 \cdot 2H_2O$ dissolved in 100 ml of np H_2O . Solution III contains 1.37 g of K_2HPO_4 dissolved in 100 ml of np H_2O .

The 1000X trace element stock (per liter) contains 29 g of $Na_2EDTA \cdot 2H_2O$ (sodium ethylenediamine tetraacetate) dissolved in np H_2O and adjusted to pH 8 with KOH. The following

Fig. 4. Growth of *Archaeoglobus* in 40-liter carboys and serum vials. Panel A: A 40-liter glass carboy heated to 80°C with a heating belt can be used to grow *A. fulgidus*. Sterile, anoxic gas is delivered to the carboy via neoprene tubing and waste gas is removed with constant flushing. Panel B: A colony of *A. fulgidus* in Gelrite agar in a stoppered tube appears black due to precipitation of FeS. Panel C: Serum bottles hold 50–100 ml of medium. Unreduced medium is pink (right bottle) due to oxidation of resazurin, which is colorless when reduced (middle bottle). A growing culture of *A. fulgidus* has a greenish appearance. Cells are transferred to fresh medium using a sterile, N₂-flushed syringe.

are added to the solution: 5 g of MnSO₄ · 6H₂O, 1.8 g of CoCl₂ · 6H₂O, 1 g of ZnSO₄ · 7H₂O, 0.11 g of NiSO₄ · 6H₂O, 0.1 g of CuSO₄ · 5H₂O, 0.1 g of H₃BO₃, 0.1 g of KAl(SO₄)₂ · 12H₂O, 0.1 g of Na₂MoO₄ · 2H₂O, 0.1 g of Na₂WO₄ · 2H₂O, 0.05 g of Na₂SeO₃, and 0.01 g of V₂O₅.

For a defined medium, 10 ml of Wolfe's vitamin mixture can be added in place of yeast extract (Balch et al., 1979). Wolfe's vitamin mixture contains (per liter) 10 mg of pyridoxine, 5 mg each of thiamine HCl, riboflavin, nicotinic acid, DL-calcium pantothenate, *p*-aminobenzoic acid, and lipoic acid, 2 mg each of biotin and folic acid, and 0.1 mg of cyanocobalamin.

Preservation

Fresh cultures of *A. fulgidus* can be prepared from frozen cell pellets (–80°C), liquid stocks, or

a colony from a roll tube. For routine manipulations, *A. fulgidus* can be grown in 50 ml (in a 100-ml serum vial) of STL medium for 1–2 days, then stored at room temperature or 4°C. Liquid stocks should be transferred to fresh medium every 2–3 weeks although growth can be obtained from cells stored at 4°C after 2–3 years. Typically, a 5% (vol) inoculum of cells is transferred to fresh medium using a N₂-flushed sterile syringe and anaerobic techniques.

Genetics

The 2.178 Mbp single circular chromosome of *Archaeoglobus fulgidus* VC-16 has been sequenced and annotated (Klenk et al., 1997; The Institute for Genome Research, *Archaeoglobus fulgidus* DSM4303 Genome page). It is estimated that there are 2436 open

reading frames (ORFs) that cover $\approx 92\%$ of the genome with about 1.1 ORF per kb. Analysis of the genome reveals extensive gene duplication, which likely contributes to the *A. fulgidus* genome being larger than the *Methanocaldococcus jannaschii* genome. The duplicated genes are not identical and likely have slightly different functions. Hence, gene duplication may have provided an evolutionary advantage as a mechanism for increasing physiological diversity. Of the 2436 ORFs, 651 are predicted to encode conserved proteins of unknown function, 428 of which are also found in the genome of *M. jannaschii*. Another 639 have no match in the databases.

The average gene is 822 bp, making the average protein about 30,000 daltons. Predicted polypeptides of *A. fulgidus* range from M_r 1939 to 266,571. The average gene size is similar to that of *M. jannaschii*, but smaller than the average eubacterial gene. While overall the genome has a DNA base composition of 48.5 mol% G+C, some lateral transfer of DNA may have occurred because three regions have low G+C content (<39 mol%) and two have high G+C content (>53 mol%). Low G+C regions contain genes that encode enzymes involved in lipopolysaccharide synthesis, while the high G+C regions contain genes for large ribosomal proteins, heme biosynthesis, and transporters. There is evidence of lateral transfer of DNA from *A. fulgidus* to eukaryotic cells. The malic enzyme of *Entamoeba histolytica*, which decarboxylates malate to pyruvate, appears to have originated with *A. fulgidus* (Field et al., 2000).

While a typical *A. fulgidus* gene initiates with ATG, 22% begin with GTG and 2% begin with TTG. No inteins have been found in *A. fulgidus* although, like in other Archaea, five of the 46 tRNAs carry 15–62-bp introns. The introns are thought to be removed by the intron excision enzyme EndA. Many small nonmessenger (SN) RNAs have been characterized from *A. fulgidus* (Tang et al., 2002). Some of these SN RNAs originated from rRNA splicing, but many were complementary to or overlapping with an ORF. While the development of genetic tools in *A. fulgidus* is in its infancy, one plasmid, pGS5, has been isolated from *A. profundus* strain AV18. The plasmid pGS5 is 2.8 kb and negatively supercoiled (Lopez-Garcia et al., 2000). No phage has been found for members of the genus *Archaeoglobus*.

Archaeoglobus fulgidus contains 40 ATP-binding subunit members of the superfamily of ATP-binding cassette (ABC) transporters for arsenite, Fe^{+2} , Fe^{+3} , proline, ribose, lactate, sulfate, hexuronate, and Cu^{+2} , to name a few. As might be expected for a marine organism, *A.*

fulgidus produces a number of proteins that regulate ionic homeostasis. These include transporters for Na^+ , Fe^{+2} , Fe^{+3} , NO_3^- , and SO_4^{-2} , as well as transporters to eliminate toxic compounds such as copper, arsenite and cyanate.

DNA replication in *A. fulgidus* involves DNA polymerases that are related to the Δ polymerase of eukaryotes. Unlike other Archaea, *A. fulgidus* also encodes a homolog of the ϵ subunit of *E. coli* PolIII, which is involved in proofreading. Several DNA repair enzymes also exist, including a eukaryotic-like Rad25, exodeoxynuclease III, reverse gyrase, and topoisomerase VI. *Archaeoglobus fulgidus* contains a novel type of uracil DNA glycosylase, which is involved in repair of uracil that arises in DNA after hydrolytic deamination of cytosine (Sandigursky and Franklin, 2000; Chung et al., 2001). The product of *nfi* is a deoxyinosine-specific endonuclease which can repair DNA lesions that occur after spontaneous deamination of deoxyadenosine (Liu et al., 2000). Although the *nfi* gene encodes a homolog of endonuclease V from *E. coli*, it is a unique protein in that it recognizes only deoxyinosine, in contrast with the *E. coli* enzyme.

A gene encoding a homolog of the bacterial RecA and eukaryotic Rad51 has been identified from the *A. fulgidus* genome. The *A. fulgidus* *radA* gene was expressed in *E. coli*, and the biochemical properties of purified RadA were compared with RadA proteins from other Archaea. Like the *Desulfurococcus amylolyticus* RadA protein, the *A. fulgidus* RadA is stable at high temperatures. RadA catalyzes DNA-stimulated ATP hydrolysis, D-loop formation and DNA strand exchange at 60–70°C (McIlwraith et al., 2001). The 37-kDa RadA protein does not bind double-stranded (ds)DNA, but forms filaments on single-stranded (ss)DNA. In solution, RadA forms ring-like structures.

Genes encoding homologs of bacterial-like transcription activators, such as Lrp, MerR, TetR, and PhoU, and sensor-kinase response regulators (two-component family) are abundant in *Archaeoglobus* (Klenk et al., 1997). In contrast, homologs of transcription factors (such as σ^{54} , MetJ, NusB, and Rho terminator) have not been found (Kyrpides and Ouzounis, 1999). As is the case for other Archaea, *A. fulgidus* has genes encoding eukaryotic-like initiation factors TFIIB, TFIID, and TFIIE α , small subunits of RNA polymerase (RPB5, RPB6, RPB8, RPB10, and RPB12), the large universal RNA polymerase subunits, and archeal histones. *Archaeoglobus fulgidus* differs from methanogens whose genomes have been sequenced in that it encodes a homolog of the eukaryotic TATA-binding protein (TBP)-interacting protein 49 and Silent Information Regulator (Sir2, the nicotine adenine dinucleotide [NAD]-dependent protein

deacetylase that is a eukaryotic transcriptional silencer). In *A. fulgidus*, the Sir2 protein may play a role in cell-cycle progression and genome integrity. Eukaryotic-like transcription factor domains, such as the MADS box or homeoboxes, have not been found.

Ecology and Environmental Stress

Extremophiles have characteristics that allow them to thrive under environmental conditions that are lethal to most known cultured organisms. In particular, hyperthermophiles have developed cellular structures to withstand adverse conditions of heat. Enzymes can be stabilized at high temperature by adopting particular protein conformation, increased substrate turnover, molecular chaperones and/or stabilizing molecules.

A comparison of the stability of the enzymes from *A. fulgidus* suggests that different methods are employed by the cell to stabilize different enzymes. An enzyme such as the D-lactate dehydrogenase seems to have stabilization imprinted in the primary amino acid structure (e.g., recombinant protein half-life of 105 minutes at 83°C was similar to that of the native protein) whereas the native reduced nicotinic adenine dinucleotide (NADH) oxidase is much more thermally stable than the recombinant form, suggesting stabilizing components may be important (Reed and Hartzell, 1999; Reed et al., 2001). The L-malate dehydrogenase carries a deletion of a specific loop at the dimer-dimer contact region, which may ensure that the dimeric form is maintained under high temperature (Madern et al., 2001), again suggesting that primary sequence dictates structural stability. The catalase-peroxidase uses turnover for stability. The catalase has a very high turnover number (the highest reported) even though stability is rather low in the presence of peroxide (Kengen et al., 2001).

Substrates, chaperones and solutes also play a critical role in stabilizing structures at high temperatures. Although *A. fulgidus* does not contain a *dnaK* (HSP70) homolog, it does have two genes that encode α and β subunits of the TCP-1 chaperone family (Klenk et al., 1997). Solute also play a role in thermal stabilization of cellular components. For example the N⁵, N¹⁰ methenyl tetrahydromethanopterin (H₄MPT) cyclohydrolyase from *A. fulgidus* requires relatively high concentrations of K₂HPO₄ (1 M) for optimal thermostability at 90°C (Klein et al., 1993). The N⁵, N¹⁰ methylene H₄MPT reductase is rapidly inactivated when incubated at 80°C; however, activity is stabilized in the presence of either substrate (F₄₂₀ [0.2 mM] or methylene-H₄MPT [0.2 mM]) or molecules such as albumin (1 mg/

ml) or KCl (0.5 M; Schmitz et al., 1991). Compatible organic solutes such as trehalose or α -glutamate, which are important for mesophile stability, accumulate in thermophilic or hyperthermophilic archaea. In addition to these, the heat stable solute diglycerol phosphate (1,1'-diglycerol phosphate) appears to be unique to *A. fulgidus* (Lamosa et al., 2000). Diglycerol phosphate production by *A. fulgidus* increases in concentration as the salinity and temperature of the growth medium increase (Martins et al., 1997; Lamosa et al., 2000). Diglycerol phosphate acts by protecting proteins against denaturation as opposed to refolding denatured proteins. Diglycerol phosphate remains stable at 95°C for at least 3 hours and can stabilize enzymes from mesophilic organisms at thermophilic temperatures (50–60°C). The *A. fulgidus* inositol-1-phosphate synthase (AF1794) is a class II aldolase that catalyzes the irreversible conversion of D-glucose 6-phosphate to L-*myo*-inositol 1-phosphate (Chen et al., 2000). This inositol (a ring-containing compound) is a common hyperthermophilic archaeon osmolyte and may also be an important response solute to stress associated with supraoptimal temperature or high salinity.

Although *A. fulgidus* is a strict anaerobe, it has the ability to survive exposure to oxygen (Beeder et al., 1994; LaPaglia and Hartzell, 1997). While some *A. fulgidus* enzymes, such as the D-lactate dehydrogenase, are not adversely affected by oxygen (Reed and Hartzell, 1999), others, such as formyl methanofuran dehydrogenase, are rapidly inactivated in the presence of oxygen (Schmitz et al., 1991). One mechanism of protection and recovery from oxygen exposure may be provided by the enzymatic reduction of oxygen in the cellular environment. *Archaeoglobus fulgidus* has several NADH oxidases (Nox) that are expressed constitutively and are located in the periplasmic space (between the membrane and the S-layer), which may establish a first line of defense against O₂ (Pagala et al., 2002). One NADH oxidase, the 47-kDa NoxA2 (AF0395), carries out bivalent oxygen reduction with the evolution of H₂O₂ (Reed et al., 2001) and H₂O. NoxA2 is stable in oxygen and at high temperatures (83°C) for up to 35 hours (Reed et al., 2001). Taken together, these findings hint that NoxA2 may be involved in detoxification of oxygen under conditions of oxidative stress.

Archaeoglobus fulgidus also encodes proteins that are homologous to *Desulfovibrio* proteins that have been shown to reduce O₂ to H₂O (Abreu et al., 2000b). These include a flavoprotein rubredoxin and rubredoxin/oxygen oxidoreductase. The *A. fulgidus* genome does not contain a gene predicted to encode a canonical superoxide dismutase (SOD) but instead

appears to have an independent mechanism to protect itself from toxic oxygen products such as superoxide ($O_2^{\cdot-}$) and H_2O_2 . A small (14.5 kDa), soluble, blue-colored, iron-containing protein named “neelaredoxin” (Nlr), which was previously identified in *Desulfovibrio gigas*, has been identified in *A. fulgidus* and is able to reduce and dismutate $O_2^{\cdot-}$ efficiently (Abreu et al., 2000a; Abreu et al., 2001; Abreu et al., 2002). The products of the reaction of $O_2^{\cdot-}$ and neelaredoxin are H_2O_2 or H_2O and O_2 . The reductase activity may allow the cell to eliminate $O_2^{\cdot-}$ by a reduced nicotinamide adenine dinucleotide phosphate (NAD[P]H)-dependent pathway, whereas the dismutation activity allows the cell to detoxify $O_2^{\cdot-}$ independently of the cell redox status. The electron donor for neelaredoxin-mediated reduction of $O_2^{\cdot-}$ to H_2O_2 involves an NADH oxidase present in *A. fulgidus* extracts (Abreu et al., 2000a).

The cytotoxic H_2O_2 generated by NoxA2 and Nlr-dependent reactions can be catabolized by the catalase-peroxidase (*perA* gene-AF2233; Kengen et al., 2001). The catalase activity strongly exceeds the peroxidase activity, and combined NoxA2 and catalase activity can decrease the oxygen content to half ($O_2 + 2NADH \leftrightarrow H_2O_2 + 2NAD^+$; $H_2O_2 \leftrightarrow H_2O + \frac{1}{2}O_2$, respectively). The catalase is active only under normal physiological conditions (pH 5.5–7 and 40–80°C), whereas the peroxidase ($AH_2 + H_2O_2 \leftrightarrow A + 2H_2O$) functions optimally during stages that might be considered environmental stress (70–90°C and pH 4–5), when a decrease in oxygen by the catalase only (incomplete oxygen removal) might be inadequate for cell survival. Although the recombinant peroxidase enzyme exhibits high thermostability, rapid inactivation occurs in the presence of H_2O_2 unless a proton donor is present.

Many microorganisms, including the archaea, form biofilms as a common stress response mechanism. *Archaeoglobus fulgidus* forms a morphologically variable biofilm containing protein, polysaccharide, and metals in response to environmental stresses induced by extremes of pH and temperature, nutrient changes, and exposure to metals, antibiotics, xenobiotics, or oxygen (LaPaglia and Hartzell, 1997). The cells within the biofilm have increased tolerance to an otherwise toxic environmental condition, suggesting that cells may produce biofilms to concentrate cells in a protective barrier and, in some cases, to store nutrients.

Metabolism

Archaeoglobus fulgidus grows well using D-lactate, L-lactate or pyruvate, but not acetate, as

a source of carbon and energy (Fig. 5). *Archaeoglobus fulgidus* can also use oxaloacetate, formate, or CO_2/H_2 as electron and carbon donor (Stetter et al., 1987). *Archaeoglobus fulgidus* strain VC-16 is reported to grow on substrates including glucose, formamide, casamino acids, peptone, casein, meat extract, yeast extract, cell homogenates, methanol, ethanol, formate, starch and gelatin; however, growth rates are minimal compared to those on the previously mentioned substrates (Stetter et al., 1987; Stetter, 1988). Additional reports show that glucose is not utilized by *A. fulgidus* VC-16 and that neither an uptake-transporter nor a catabolic pathway is identified at the genetic level for glucose (Klenk et al., 1997), which is not surprising considering most sulfate-reducing bacteria typically are unable to utilize glucose. Although growth on acetate has not been demonstrated, the genes for acetate utilization, such as acetyl CoA synthetase, are present in *A. fulgidus* VC-16. Moreover, genes encoding oxidoreductase enzymes that could generate energy from nitrate, nitrite and polysulfide also are present. The presence of multiple enzymes for β -oxidation and ferredoxin-dependent oxidoreductases in the genome suggests that under appropriate conditions, *A. fulgidus* uses hydrocarbons and organic acids as a source of carbon. An acyl-CoA ligase related to FadD may play a role in the import of long-chain fatty acids across the membrane (Klenk et al., 1997).

Archaeoglobus fulgidus is able to synthesize the amino acids, vitamins and cofactors, purines and pyrimidines that it needs to sustain growth, but it lacks biochemical pathways that are common to many bacteria. For example, most if not all of the genes for the pentose-phosphate, Entner-Doudoroff, glycolysis and gluconeogenesis pathways are absent (Klenk et al., 1997). However, there is evidence that *A. fulgidus* uses atypical enzymes to carry out certain reactions within these pathways. For example, *A. fulgidus* does not have a fructose 1,6-bisphosphatase (FBPase), yet it produces an inositol monophosphatase (IMPase) that has FBPase activity (Rashid et al., 2002). Interestingly, *A. fulgidus* does not have typical bacterial polysaccharide biosynthetic machinery, but it does encode glycosyl transferases, suggesting the ability to make polysaccharides. The products of the ≈ 78 amino acid biosynthetic genes appear to form pathways that are similar to those found in *Bacillus subtilis*. Surprisingly, the genes for synthesis of biotin and pyridoxine are missing from the genome even though both compounds can be detected in cell extracts (Noll and Barber, 1988). Hence, these components may also be produced by an alternative pathway.

Fig. 5. Energy production using lactate as a source of carbon and energy. Lactate is converted to pyruvate by D- or L-lactate dehydrogenase. Electrons from catabolism of lactate are used to reduce sulfate to sulfide, and release of protons generates a proton motive force (PMF) that is used to make ATP via ATPase. Sat = sulfate adenylyltransferase (ATP sulfurylase; AF1667; 53 kDa); AprAB = adenylylsulfate reductase subunits A (AF1670; 73 kDa) and B (AF1669; 17 kDa); and DsrABD = sulfite reductase (α = AF0423, 47.5 kDa, β = AF0424, 41.8 kDa, and γ = AF0425, 8.8 kDa). Mer = N⁵,N¹⁰-methylene tetrahydromethanopterin reductase (*mer-1* = AF1066, *mer-2* = AF1196); Mtd = N⁵,N¹⁰-methylene tetrahydromethanopterin dehydrogenase (AF0714); Mch = N⁵,N¹⁰-methenyltetrahydromethanopterin cyclohydrolase; Ftr = formylmethanofuran H4MPT formyltransferase (*ftr-1* = AF2073 and *ftr-2* = AF2207); FwdA-G = formylmethanofuran dehydrogenase (A = AF1930, B-1 = AF1650, B-2 = AF1929, C = AF1931, D-1 = AF1651, D-2 = AF1928, E = AF0177, F = AF1644, and G = AF1649). *Archaeoglobus fulgidus* also encodes Mtr (N⁵-methyltetrahydromethanopterin:coenzyme M methyltransferase [AF0009; not shown]).

Archaeoglobus fulgidus lacks a complete citric acid cycle. Key metabolic intermediates are produced from a partial cycle to synthesize molecules such as amino acids and to generate reducing power (reduced nicotinamide adenine dinucleotide phosphate [NADPH]). For example, enzymes required for reductive formation of succinate from oxaloacetate and oxidative formation of 2-oxoglutarate (α -ketoglutarate) from oxaloacetate and acetyl-CoA are present (Steen et al., 2001). *Archaeoglobus fulgidus* has an NADP⁺-dependent isocitrate dehydrogenase (AF0647) that catalyzes the formation of 2-oxoglutarate, CO₂ and NAD⁺ from D-isocitrate, although the enzyme also has specificity for NAD⁺, resulting in low 2-oxoglutarate oxidation (Steen et al., 1997).

The L-malate dehydrogenase (AF0855) from *A. fulgidus* catalyzes the reversible reduction of oxaloacetate to L-malate with NADH (Langelandsvik et al., 1997). The rate of reduction of oxaloacetate with NADH is tenfold greater than malate oxidation with NAD⁺, suggesting a preferred biosynthetic role. Interestingly, the enzyme shows higher amino acid sequence homology to lactate dehydrogenases than to other malate dehydrogenases, although L-malate and L-lactate dehydrogenases belong to the same family of NAD-dependent enzymes (Maden et al., 2001).

Archaeoglobus fulgidus uses inorganic molecules or amino acids as a source of nitrogen. No genes for N₂ fixation have been found. NADP⁺-specific glutamate dehydrogenase (EC 1.4.1.4)

purified from *A. fulgidus* strain 7324 has a higher affinity for 2-oxoglutarate than for glutamate, which suggests its preferred role in the biosynthesis of glutamate (Aalen et al., 1997). The glutamate dehydrogenase connects the citric acid cycle with nitrogen assimilation by reductive amination of 2-oxoglutarate to glutamate. Although the N-terminal sequence showed a high degree of similarity to those of glutamate dehydrogenases from *Pyrococcus* spp. and *Thermococcus* spp., *A. fulgidus* strain VC-16 does not appear to have a homologous glutamate dehydrogenase (Klenk et al., 1997). A summary of kinetic parameters for a subset of enzymes from *A. fulgidus* is presented in Table 2.

LACTATE UTILIZATION In general, when lactate is the electron and carbon donor in sulfate-reducing bacteria (SRB), it is converted to pyruvate and subsequently to acetate and CO₂ with the release of protons and molecular hydrogen. Molecular hydrogen likely passes through the membrane where periplasmic hydrogenases convert H₂ to H⁺. Electrons are transferred to a *c*-type cytochrome with subsequent sulfate reduction, while the accumulation of protons (proton motive force [PMF]) is used to generate energy as ATP. In *A. fulgidus*, ATP is generated via F₄₂₀H₂:quinone oxidoreductase and V₀V₁ATPase (Klenk et al., 1997). When hydrogen production is unfavorable, the electron balance is maintained in the cell by the production of H₂ by way of the iron-sulfur electronegative electron carrier ferredoxin that transfers electrons to protons via the hydrogenase. Elucidation of the process of electron transport is currently ongoing in *A. fulgidus*.

The lactate dehydrogenases, which oxidize lactate to pyruvate, are essential for the growth of dissimilatory sulfate reducers on lactate as a sole electron donor. *Archaeoglobus fulgidus* can use either D- or L-lactate as its sole electron donor and carbon source, and it makes a lactate dehydrogenase specific for D-lactate and another enzyme specific for L-lactate (Reed and Hartzell, 1999). The D-lactate dehydrogenase (Dld) from *A. fulgidus* is similar to the Dld from *Kluyveromyces lactis*. Like in the yeast enzyme, zinc is tightly bound to the Dld and is thought to be essential for catalytic activity. Potential electron acceptors during D-lactate oxidation include cytochromes or quinones. *Archaeoglobus fulgidus* produces *b*- and *c*-type cytochromes (Kunow et al., 1994; Mander et al., 2002) and a 7-menaquinone (Tindall et al., 1989), which might accept electrons from Dld. Although Dld does not transfer electrons to horse-heart cytochrome *c*, it may transfer electrons to the *A. fulgidus* membrane-associated 16-kDa cyto-

chrome *c*, which is similar in spectral properties and molecular mass to the *c*₅₅₃-cytochrome from bacterial SRB.

L-Lactate is oxidized by the *A. fulgidus* membrane-associated L-lactate dehydrogenase (Möller-Zinkhan et al., 1989; Reed and Hartzell, 1999). Electrons are transferred to dimethylnaphthoquinone in vitro suggesting that a menaquinone is the electron acceptor in vivo. *Archaeoglobus* contains a menaquinone as its major respiratory lipoquinone in its cell membrane (Tindall et al., 1989). The 2-methyl-3-I,II,III,IV,V,VI,VII-tetradecahydro-heptaprenyl-1,4-naphthoquinone (MK-7H₁₄) has seven isoprenyl units and fully saturated side chains and a minor lipoquinone with six isoprenyl units and fully saturated side chains. This differs from the lipoquinones from bacterial sulfate reducers that typically have fully unsaturated or dihydrogenated terminal isoprenoid units. Finally pyruvate is oxidized to acetyl-CoA, with ferredoxin transferring electrons by the *A. fulgidus* pyruvate:ferredoxin oxidoreductase (Kunow et al., 1995).

The constitutively expressed integral-membrane-bound Dld extends into the periplasm, with its flavin adenine dinucleotide (FAD)-binding pocket facing the S-layer. The Dld colocalizes with the periplasmically-located soluble NADH oxidase, NoxA2 (Pagala et al., 2002). The genes encoding these two interacting proteins are cotranscribed, which suggests that NoxA2 may also be involved in energy-yielding reactions (Reed et al., 2001). NoxA2 has diaphorase activity for the reduction of the electron-carriers including cytochrome *c* and menadione, suggesting that under certain circumstances the *A. fulgidus* membrane-associated cytochrome *c* may accept electrons from NoxA2. In addition, because NoxA2 can reduce O₂, it may play a role in protecting the cell from exposure to O₂, as described earlier.

CARBOHYDRATE UTILIZATION *Archaeoglobus fulgidus* strain 7324 is the only sulfate-reducing prokaryote found to utilize starch (i.e., act on glucose α 1–4 linkage). Strain 7324 grows as well on starch as an energy and carbon source as do *A. fulgidus* strains 7324 and VC16 on lactate (Labes and Schönheit, 2001). Starch (1 mole of glucose equivalent) is oxidized with sulfate to approximately 2 moles of acetate, 2 moles of CO₂ and 1 mole of H₂S using acetyl-CoA ADP-forming synthetase and enzymes of a modified Embden-Meyerhof pathway. Cells grown on starch do not, however, fluoresce blue-green, which is evidence for limited deazaflavin factor F₄₂₀ (<0.03 nmol/mg protein). In contrast, lactate (1 mole) is completely oxidized to 3 moles of

Table 2. Characteristics of selected enzymes from *A. fulgidus*.^a

Enzyme	Structure (subunit kDa)	Optima		Cofactors and ions	Activity

CO₂ and 1.5 moles of H₂S, and lactate-grown cells contain high amounts of F₄₂₀ (0.6 nmoles/mg protein), indicating utilization of the reverse-methanogenesis related enzymes.

A subset of Embden-Meyerhof pathway enzymes has been detected in extracts of starch-grown cells (Labes and Schönheit, 2001). Present were phosphoglucose isomerase, which converts α -D-glucose 6-phosphate to β -D-fructose 6-phosphate, and fructose-1, 6-diphosphate aldolase, which produces D-glyceraldehyde 3-phosphate from β -D-fructose 1,6-diphosphate. Conventional reactions are carried out by the triose-phosphate-isomerase (dihydroxyacetone-phosphate conversion to D-glyceraldehyde 3-phosphate), phosphoglycerate mutase (3-phospho-D-glycerate conversion to 2-phospho-D-glycerate), enolase (2-phospho-D-glycerate to phosphoenol-pyruvate) and pyruvate kinase (phosphoenol-pyruvate to pyruvate). Although glyceraldehyde-3-phosphate dehydrogenase activity was present, phosphoglycerate kinase activity was not detected. Hence, D-glyceraldehyde 3-phosphate-dependent oxidation does not proceed by 1,3-bisphosphate D-glycerate. Glyceraldehyde-3-phosphate:ferredoxin oxidoreductase (GAP:FdOR) is believed to be the enzyme responsible for D-glyceraldehyde 3-phosphate oxidation to 3-phospho-D-glycerate. The GAP:FdOR enzyme was not present in lactate-grown cells but was present in starch-grown cells.

ATP does not serve as a phosphoryl donor for the ADP-dependent hexokinase (ADP-HK) and for the 6-phosphofructokinase (ADP-PFK). The K_m for ADP and glucose with ADP-HK is 0.2 and 2.6 mM, respectively, and the K_m for ADP and fructose 6-phosphate with ADP-PFK is 1 and 3.3 mM, respectively. ATPase activity is high in starch-grown cells to supply the required ADP. Overall specific activities of ADP-HK, ADP-PFK, GAP:FdOR, and PK are significantly higher in starch-grown cells than in lactate-grown cells, indicating induction of these enzymes during starch catabolism.

The pyruvate:ferredoxin oxidoreductase converts pyruvate to acetyl-CoA. The conventional enzymes involved in conversion of acetyl-CoA to acetate (phosphate acetyltransferase and acetate kinase) have not been detected by enzymatic assay (Möller-Zinkhan and Thauer, 1990), nor are there genes encoding homologs of these enzymes in the genome (Klenk et al., 1997). *Archaeoglobus fulgidus* does however make an ADP-forming acetyl coenzyme A synthetase (ACD), a novel enzyme found in Archaea and eukaryotic protists that is involved in acetate formation and energy production. ACD converts acetyl-CoA to acetate in a single step (acetyl-

CoA + ADP + Pi acetate + ATP + CoA; Musfeldt and Schönheit, 2002). ACD also can utilize acyl-CoA esters to produce ATP and the corresponding acid. Two ACD ORFs (AF1211 and AF1938) of *A. fulgidus* each generate homodimers (ACD I and ACD II, respectively) of about 140 kDa composed of two identical 70-kDa subunits. ACD I has high substrate specificity toward acetate (k_{cat}/K_m 0.4 $\mu\text{M}^{-1}\text{s}^{-1}$) and acetyl-CoA (k_{cat}/K_m 9.2 $\mu\text{M}^{-1}\text{s}^{-1}$), whereas ACD II has higher specificity for phenylacetate (k_{cat}/K_m 0.0012 $\mu\text{M}^{-1}\text{s}^{-1}$) and phenylacetyl-CoA (k_{cat}/K_m 0.14 $\mu\text{M}^{-1}\text{s}^{-1}$) but not acetyl-CoA (k_{cat}/K_m <0.000046 $\mu\text{M}^{-1}\text{s}^{-1}$). Physiological roles for these enzymes in *A. fulgidus* have been proposed on the basis of their similarity with the *Pyrococcus furiosus* enzymes. ACD I is predicted to play a role in utilization of acetyl-CoA derived from carbohydrates whereas ACD II is involved in the degradation of aryl-CoA esters derived from aromatic 2-keto acids. Both enzymes are thought to participate in degradation of branched chain acyl-CoAs derived from branched chain 2-keto acids (Musfeldt and Schönheit, 2002).

Acetate is an end product of starch metabolism. Hence, although the acetyl-CoA/CO-dehydrogenase (which converts acetyl-CoA to CO₂ via CO) is present, it must be inactive. The F₄₂₀-dependent enzymes are linked to the acetyl-CoA/CO-dehydrogenase pathway; their apparent absence in cells grown on starch suggests that they limit the rate of acetyl-CoA/CO-dehydrogenase activity. The production of F₄₂₀ appears to be substrate regulated. This is substantiated by the limited production of F₄₂₀ and F₄₂₀-dependent dehydrogenases for *A. fulgidus* VC-16 grown on CO₂ and for the chemolithoautotroph *A. lithotrophicus* (Vorholt et al., 1995).

Archaeoglobus fulgidus cannot degrade cellulose (glucose β [1–4] linkage; Bayer et al., 1999) because it lacks a known glycosyl hydrolase gene. However, it has two ORFs that contain cohesin domains and one with a dockerin domain, which are characteristic of proteins in cellulosome complexes used by cellulolytic microorganisms to hydrolyze plant cell wall polysaccharides. It is unclear what function(s) the putative cohesin and dockerin-containing proteins play in *A. fulgidus*.

CARBON FIXATION *Archaeoglobus fulgidus* is able to oxidize lactate to three carbon dioxide molecules via pyruvate and acetyl-CoA using the reverse methanogen C₁ and carbon monoxide dehydrogenase pathways (Möller-Zinkhan and Thauer, 1990). As mentioned previously, in *A. fulgidus* the enzymes and cofactors associated with the reduction of CO₂ to methane by meth-

anogens are used to oxidize the methyl group from acetyl-CoA to CO₂ (Möller-Zinkhan et al., 1989). In addition, *A. fulgidus* has an acetyl-CoA decarbonylase/synthase (ACDS) multienzyme complex that catalyzes the reversible cleavage and synthesis of acetyl-CoA from CO₂ (Dai et al., 1998). The ACDS complex is the key enzyme component of the acetyl-CoA catabolism pathway and is structurally and functionally similar to the ACDS complex found in methanogens. The C₁-carrier cofactor in these reactions is the tetrahydromethanopterin (H₄MPT, a folate analog) as in methanogens (Gorris et al., 1991); the sulfate-reducing bacteria use tetrahydrofolate as a C₁ carrier. The H₄MPT is typically associated with hydrogenotrophs whereas acetotrophs typically contain sarcinapterin (Gorris et al., 1991). The ACDS complex in *A. fulgidus* is also able to utilize tetrahydrosarcinapterin (H₄Spt) and *Methanosarcina* ferredoxin in catalysis of acetyl-CoA synthesis (Dai et al., 1998).

During lactate catabolism, acetyl-CoA is cleaved into two C₁-units, one of which is oxidized to CO₂ via CO with the ACDS complex (acetyl-CoA + H₄MPT + 2Fd_{ox} ↔ CH₃-H₄MPT + CO₂ + 2Fd_{red}). This reaction is reversible during autotrophic growth and catalyzes the overall synthesis of acetyl-CoA according to the following reaction: CO₂ + 2 Fd_{red}(Fe²⁺) + 2H⁺ + CH₃H₄Spt + CoA ↔ acetyl-CoA + H₄Spt + 2Fd_{ox}(Fe³⁺) + H₂O (Fd = ferredoxin; CH₃-H₄Spt and H₄Spt denote N⁵-methyl-tetrahydrosarcinapterin and tetrahydrosarcinapterin, respectively). The ACDS enzyme comprises a significant level (5%) of the total soluble cell protein, suggesting that it may be required to ensure a flux of electrons for sulfate reduction. The corrinoid, 5' methylbenzimidazolyl cobamide, found in sulfate-reducers but not methanogens, represents a significant component in *A. fulgidus* due to its involvement in this reaction (Dai et al., 1998).

The other C₁-unit of acetyl-CoA is transferred to H₄MPT and electrons are transferred to the 5-deazaflavin coenzyme F₄₂₀ by the N⁵, N¹⁰-methylene H₄MPT reductase (CH₃-H₄MPT + F₄₂₀ CH₂ = H₄MPT + F₄₂₀H₂; Schmitz et al., 1991; Kunow et al., 1993). The reduced 5-deazaflavin coenzyme (F₄₂₀H₂) is probably oxidized by the membrane-bound F₄₂₀H₂ quinone oxidoreductase, with electrons transferred to menaquinone (Kunow et al., 1994). F₄₂₀H₂ quinone oxidoreductase is encoded by the 11-gene *fqo* gene cluster (*fqo* J, K, M, L, N, A, B, C, D, H, I, F) and is involved in energy conservation (Bruggemann et al., 2000). The amino acid sequences of all other genes (except *fqoF*) show homology to NADH-quinone oxidoreductases from prokaryotes and eukaryotes, suggesting that the F₄₂₀ H₂-dependent and the NADH-dependent enzymes are

functional equivalents. The 39-kDa protein product of the *fqoF* gene is responsible for oxidation of F₄₂₀. The C₁-unit is oxidized to CO₂ sequentially by the methylene H₄MPT dehydrogenase, transferring electrons to coenzyme F₄₂₀ 5,10-methylene-H₄MPT (CH₂ = H₄MPT) + F₄₂₀ + H⁺ ↔ 5, 10-methenyl-H₄MPT (CH ≡ H₄MPT⁺) + F₄₂₀H₂; Kunow et al., 1993; Schwörer et al., 1993), N⁵, N¹⁰-methenyl-H₄MPT cyclohydrolase (5, 10-methenyl) (CH ≡ H₄MPT⁺ + H₂O ↔ 5-formyl-H₄MPT (CHO-H₄MPT) + H⁺; Klein et al., 1993), formyl methanofuran-H₄MPT formyltransferase (5-formyl-H₄MPT (CHO-H₄MPT) + methanofuran (MFR) ↔ formyl-MFR CHO-MFR + H₄MPT; Schwörer et al., 1993), and formyl methanofuran dehydrogenase (formyl-MFR (CHO-MFR + X + H₂O ↔ CO₂ + MFR + XH₂; electron acceptor has not been identified; Schmitz et al., 1991).

Most anaerobes in the Archaea capture (fix) CO₂ via the acetyl CoA or reverse citric acid cycle pathways. Hence, finding two genes that are predicted to encode a ribulose 1,5-bisphosphate carboxylase/oxygenase (rubisco)-like protein in the *A. fulgidus* genome was surprising. *Methanococcus jannaschii* also is predicted to encode a rubisco protein, which shares 41 and 45% identity, respectively, with rubisco form 1 and 2 from *A. fulgidus*. Although the Archaea rubisco proteins share only 33% identity with the form II subunit from *Rhodospirillum rubrum* and 41% identify with the form 1 subunit from *Synechococcus*, most of the critical active site residues are present in the Archaeal proteins. The *M. jannaschii* rubisco, expressed in *E. coli*, formed a homodimer that could convert ribulose bisphosphate and CO₂ to 3-phosphoglyceric acid at a reasonable, albeit lower, rate compared with its bacterial and eukaryotic counterparts. Oxygen inhibited the reaction reversibly, although it appears to bind tightly to the enzyme. The physiological role of rubisco in either *A. fulgidus* or *M. jannaschii* is unknown, but hints to its function have come from studies with the *Chlorobium tepidum* rubisco. Like the archaeal proteins, the *C. tepidum* rubisco lacks some of the typical active site residues that are critical for function. Moreover, there is evidence that the *C. tepidum* rubisco plays a role in oxidative stress and/or sulfur metabolism (Hanson and Tabita, 2001). The similarity between the *Chlorobium* and *Archaeoglobus* rubisco subunits hints that they may have similar functions.

SULFATE REDUCTION Dissimilatory sulfate-reducing prokaryotes use sulfate, thiosulfate or sulfite as the terminal electron acceptor during anaerobic respiration. Elemental sulfur (S⁰) is

inhibitory to growth of *A. fulgidus* when other electron acceptors are present. *Archaeoglobus fulgidus* contains the complete conserved dissimilatory sulfate reduction pathway as characterized in sulfate-reducing bacteria (SRB). Phylogenetic analysis of the ATP sulfurylases, adenosine 5'-phosphosulfate (APS) reductases, and sulfite reductases suggests that the proteins became specialized for assimilatory and dissimilatory purposes prior to divergence of Archaea and Bacteria (Dahl and Trüper, 2001).

Sulfate reduction in SRB occurs in the cytoplasm and the enzymes that carry out these reactions associate with unknown membrane-associated electron carriers. During dissimilation, sulfate must first be activated by ATP to accept electrons, because reduction of sulfate to sulfite alone is not energetically favorable. Sulfate is activated to adenylylsulfate by ATP sulfurylase, the product of the *sat* gene. Sulfate adenylyltransferase (Sat) is the key enzyme in this activation for both dissimilatory and assimilatory sulfate reduction. The Sat protein is similar to homo-oligomeric adenosine triphosphate (ATP) sulfurylases from sulfur-oxidizing bacteria and sulfate assimilating organisms (Sperling et al., 1998). When expressed and purified from *E. coli*, the ATP sulfurylase is a homodimer. The ATP sulfurylase (sulfate adenylyltransferase) catalyzes the reaction of sulfate at the expense of ATP to generate APS. Inorganic pyrophosphate (PP_i) is released during this reaction. APS is reduced to AMP and sulfite (SO₃²⁻) by the *aprAB* gene products, which encode adenylylsulfate reductase. In the final six-electron transfer, sulfite is reduced to sulfide by the products of the *dsrABD* genes encoding sulfite reductase. Typically, sulfide is released as volatile hydrogen sulfide (H₂S) gas. Although *A. fulgidus* contains *cysC*, which encodes adenylylsulfate 3-phosphotransferase (APS kinase), this enzyme is not involved in dissimilatory sulfate reduction (Sperling et al., 1998).

The ATP sulfurylase (MgATP-sulfate adenylyltransferase, EC 2.7.7.4) forms a homotrimer in *A. fulgidus*, although the recombinant form is a homodimer (Dahl et al., 1990; Sperling et al., 2001). The reaction is thermodynamically unfavorable and there is evidence that activation of ATP sulfurylase by a potent inorganic pyrophosphatase (EC 3.6.1.1) helps to pull the reaction in the forward direction (Dahl et al., 1990). The recombinant form requires 0.5 M NaCl for thermal stability and has an optimal stability at >100°C, whereas the native enzyme is most stable at 90°C. The recombinant protein is tenfold less active than the native enzyme. These differences are thought to be due to incorrect folding or incorrect posttranslational modification (Sperling et al., 2001).

The native electron donor to the APS reductase (adenylylsulfate reductase, EC 1.8.99.2) is unknown, but may be a reduced menaquinone (Tindall et al., 1989). The APS reductase structural genes (*aprA* and *aprB*) form an operon with the ATP sulfurylase and an unknown 13.6-kDa cytoplasmic protein (Speich et al., 1994; Sperling et al., 2001). The APS reductase is thermostable and comprises about 1.5% of the total soluble cellular protein in *A. fulgidus* (Speich and Trüper, 1988; Dahl and Trüper, 2001). The enzyme has 1 mole of FAD bound with 8 moles of nonheme iron and 6 moles of labile sulfide per enzyme. Two distinct iron-sulfur centers exist, one of which reacts with the substrates AMP and sulfite (Lampreia et al., 1991). The two centers, which transfer two electrons from the surface of the protein to FAD, differ significantly in reduction potential (−60 and −500 mV; Fritz et al., 2002b). The reductase has been crystallized and its structures in the two-electron reduced state and with sulfite bound to FAD at 1.6-Å and 2.5-Å resolution, respectively, were determined (Fritz et al., 2002b). Sulfite binds to FAD to form a covalent FAD-N5 sulfite adduct (Fritz et al., 2002a). The architecture of the active site suggests that catalysis involves a nucleophilic attack of the N5 atom of FAD on the sulfur of APS. The structure of the APS reductase is very similar to that of fumarate reductase and it has been suggested that they arose from a common ancestor (Fritz et al., 2002a).

The final step of sulfate respiration, the sulfite reductase (EC 1.8.99.1) reaction, is the central energy-conserving step. The native sulfite reductase represents 0.5% of the total soluble cellular protein (Dahl et al., 1993). The green-colored enzyme contains siroheme and non-heme iron atoms and acid labile sulfide that make six [4Fe-4S] clusters, two of which bind siroheme and four of which bind ferredoxin amino acid motifs. The β subunit lacks a single cysteine residue in one of the two cluster motifs, suggesting that only the α subunit binds the siroheme-[Fe₄S₄] complex, and chemical analyses show the presence of only two sirohemes per enzyme molecule. The subunit genes are transcribed in tandem and the peptides have 25.6% amino acid sequence identity, indicating that they may have arisen by a duplication event.

ALTERNATIVE ACCEPTORS AND METAL REDUCTION *Archaeoglobus fulgidus* can use electron acceptors besides sulfate, sulfite or thio-sulfate for respiration. For example it can use the humic analog, anthraquinone-2,6-disulfonate (AQDS), as an electron acceptor (Lovely et al., 2000). Although other organisms use hydrogen as the electron donor in this reaction, in *A. fulgidus* only lactate serves as the electron donor in

AQDS reduction. The humics contain extracellular quinone moieties that can serve as electron acceptors that may in turn shuttle electrons to Fe(III) for reduction.

Iron oxidation has been well studied in organisms such as *Thiobacillus* and *Sulfolobus*, which can oxidize ferrous (Fe^{2+}) to ferric (Fe^{3+}) iron for energy, albeit very little energy is gained because $\text{Fe}^{3+}/\text{Fe}^{2+}$ is +0.77V at pH 2 and $1/2\text{O}_2/\text{H}_2\text{O}$ is +0.82V. While dissimilatory iron (Fe^{3+}) reduction is poorly understood, it is becoming more apparent that a diversity of microorganisms can reduce (and respire) iron. Hence iron (Fe^{3+}) reduction has been hypothesized to be a universal event (Vargas et al., 1998). Although organisms such as *Pyrobaculum islandicum* and *Thermotoga maritima* can grow using H_2 as electron donor and Fe(III) as electron acceptor, these conditions have not been found to support the growth of *A. fulgidus* (Vargas et al., 1998). Neither can *A. fulgidus* reduce Au(III) under conditions that favor formation of colloidal gold by *P. islandicum* (Kashefi et al., 2001).

Archaeoglobus fulgidus contains highly thermostable Fe^{3+} -EDTA reductase activity in its soluble protein fraction (Vadas et al., 1999). The ferric reductase is closely related to the NAD(P)H:FMN oxidoreductases that are associated with monooxygenases involved in oxidative degradation of aromatic or hydrocarbon compounds (Vargas et al., 1998). Dissimilatory ferric reductases catalyze the reduction of Fe^{3+} in energy metabolism, where iron is taken up as complexed Fe^{3+} and reduced to Fe^{2+} using NADPH as the electron donor during assimilation of iron into the cell. The *A. fulgidus* ferric reductase is functionally most similar to the enzymes used in assimilation; however, the high specific activity and high abundance in the cell (0.75% soluble protein) suggest that the enzyme may be involved in dissimilatory iron reduction. It is speculated that a hydrogenase on the outside of the cell membrane would generate a proton gradient and hence a PMF to generate ATP. Electrons would transfer to an NADH dehydrogenase inside the cell to generate NADH. The ferric reductase would then regenerate NAD and serve as the terminal electron acceptor in a process not unlike sulfate reduction.

The *A. fulgidus* ferric reductase (*fer* gene AF0830) appears to be a novel enzyme because it shares amino acid sequence similarity with a family of NADPH:FMN oxidoreductases but not with ferric reductases. Ferric reductase uses both NADH and NADPH as electron donors to reduce Fe^{3+} -EDTA and other complexes. Uncomplexed Fe^{3+} is not utilized as an acceptor (Vadas et al., 1999). The ferric reductase reduces FMN and FAD, but not riboflavin, with NADPH, which classifies the enzyme as a

NADPH flavin oxidoreductase. The crystal structure of recombinant *A. fulgidus* ferric reductase shows the enzyme is homologous to the FMN-binding protein from *Desulfovibrio vulgaris*, with a fold type similar to the flavin-binding domain of the ferredoxin reductase superfamily (Chiu et al., 2001). The *A. fulgidus* ferric reductase is further distinguished from the ferredoxin reductase superfamily by the absence of a Rossmann fold domain that is used to bind the NADPH. Instead, ferric reductase uses its single domain to provide both the flavin and the NADPH binding sites. Potential binding sites for ferric iron complexes are identified near the cofactor binding sites. This enzyme lacks an aromatic residue stacked against the isoalloxazine ring, which typically protects the flavin from O_2 oxidation, suggesting anaerobic development.

Summary

The biochemistry, physiology, and genome sequence of *A. fulgidus* have contributed much to our understanding of the relationship of Archaea with Bacteria and Eukarya. Proteins from *A. fulgidus*, such as Sir2 (Min et al., 2001), adenylylsulfate reductase (Roth et al., 2000), MinD (Cordell and Lowe, 2001), Sm1 and Sm2 (small nuclear ribonucleoprotein particles; Toro et al., 2002), and splicing endosome (Li and Abelson, 2000), whose homologs have been difficult to crystallize from other organisms, have yielded tractable structural data. Structural information from novel enzymes, such as ferric reductase and the IMPase/FBPase, has provided insight into the possible origins and evolution of particular active site conformations.

Thermoplasmatales

HARALD HUBER AND KARL O. STETTER

Introduction

The order Thermoplasmatales (Reysenbach, 2001) is represented by facultatively anaerobic, thermoacidophilic, autotrophic or heterotrophic organisms that are unique among the Archaea both by their morphology and by their phylogenetic position. So far, the order harbors three families, each represented by one genus: the Thermoplasmaceae (genus *Thermoplasma*; Darland et al., 1970), the Picrophilaceae (genus *Picrophilus*; Schleper et al., 1995), and the recently described Ferropasmaceae (genus *Ferroplasma*; Golyshina et al., 2000), formerly named *Ferromonas metallovorans*.

Thermoplasma spp. are devoid of a cell wall or envelope. For that reason, the genus *Thermoplasma*, which was for a long time (until 1995) the only member of the group, was first considered to be associated with the (bacterial) mycoplasmas (Darland et al., 1970; Masover and Hayflick, 1981). However, results of 16S rRNA sequence analyses revealed that *Thermoplasma* was a member of the archaeal domain (Woese and Fox, 1977; Woese et al., 1980; Woese et al., 1990). Although the sequences were quite unique, they clustered within the kingdom Euryarchaeota (Woese et al., 1990) and most calculations placed them between the Methanobacteriales and the Archaeoglobales. Furthermore, the affiliation to the Archaea was clear from a number of biochemical and molecular features (Stetter and Zillig, 1985; Langworthy and Smith, 1989). However, several characteristics were more crenarchaeotal than euryarchaeotal, like the physiology (Darland et al., 1970; Belly et al., 1973; Stetter and Zillig, 1985; Segerer et al., 1988) and the composition of the DNA-dependent RNA polymerase (Sturm et al., 1980; Zillig et al., 1982). In contrast, the requirement for polypeptide synthesis and the degree of stability of the ribosomal subunit association (Londei et al., 1986) supported the relationship to the Euryarchaeota, and the structure of the RNA polymerase of *Thermoplasma* was taken to be possibly of no phylogenetic significance (Yang et al., 1985). The lack of a cell wall as well as some other properties resembling those of mycoplas-

mas, e.g., the shape of the colonies, was therefore due to convergent evolution of these entirely unrelated groups of organisms. At present, there is no doubt that *Thermoplasma*, together with *Picrophilus* and *Ferroplasma*, represents a separate order within the domain Archaea.

Phylogeny

Based on 16S rRNA sequence data, the order Thermoplasmatales is a member of the euryarchaeotal branch of the Archaea (Woese et al., 1990). It forms an isolated cluster which branches in most calculation programs between the Methanobacteriales and the Methanomicrobiales/Halophiles (Fig. 1). However, the 16S rRNAs of all members show an unusual nucleotide sequence (for *Thermoplasma*, see Woese et al., 1980) and a high number of base exchanges in comparison to all other Archaea known so far. As a consequence the Thermoproteales exhibit low phylogenetic similarities (between 0.6 and 0.73 to all other Euryarchaeota and 0.58 to 0.67 to the Crenarchaeota). These values indicate that at the moment, no closer relatives of the members of the Thermoplasmatales are described. Within the order, the representatives of the different genera exhibit phylogenetic similarities between 0.86 and 0.89 (with the exception of the two *Thermoplasma* species, which show an identity of 98.6%).

Taxonomy

The order Thermoplasmatales (including the family Thermoplasmaceae) was first defined in the latest edition of *Bergey's Systematic Bacteriology* (Reysenbach, 2001). It is comprised of three different families, each represented by one single genus. So far, the genus *Thermoplasma* (Darland et al., 1970), the type genus for the family Thermoplasmaceae and the order Thermoplasmatales, harbors two described species: *T. acidophilum* and *T. volcanium* (Segerer et al., 1988). The type strain for *T. acidophilum* is strain 122-1B2^T (ATCC 25905^T and DSM 1728^T;

Fig. 1. Phylogenetic tree based on 16S rRNA sequences. The tree was calculated using the neighbor-joining program with Jukes-Cantor correction, which is included in the ARB package (Technische Universität, München; Ludwig and Strunk, 1997). Scale bar: 10 estimated exchanges within 100 nucleotides. Red lines = Euryarchaeota; Blue lines = Crenarchaeota; and Green lines = Bacteria.

American Type Culture Collection [ATCC], Rockville, MD, USA; Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH [DSMZ], Braunschweig, Germany) and for *T. volcanium* strain GSS1*^T (ATCC 51530^T and DSM 4299^T). The latter presents the DNA homology group 1 of *T. volcanium*. Additionally,

two further DNA homology groups within *T. volcanium* have been established: strains KD3 (representing DNA homology group 2) and KO2 (representing DNA homology group 3), which are available from the DSMZ (DSM 4300 and 4301, respectively). They do not hybridize significantly with organisms from the other groups

(Seeger et al., 1988), indicating that the organisms are genomically unrelated (Schleifer and Stackebrandt, 1983). However, owing to the lack of distinctive phenotypic features, a description of separate species was not carried out (Seeger et al., 1988). The representatives of the three homology groups are thus still treated as the single taxon, *T. volcanium*. The two *Thermoplasma* species can be distinguished by the G+C content of their genomic DNA and by DNA-DNA hybridization (Table 1). *Thermoplasma acidophilum* exhibits a G+C content of 46 mol% (Christiansen et al., 1975; Searcy and Doyle, 1975b), whereas the G+C content of *T. volcanium* is ~38 mol%. There is no significant DNA homology between the two species.

The genus *Picrophilus* represents the second family of the Thermoplasmatales, the Picrophilaceae (Schleper et al., 1996). Two *Picrophilus* species are described: *P. oshimae* (type strain: KAW 2/2^T, DSM 9789^T) and *P. torridus* (type strain KAW 2/3^T, DSM9790^T). However, since in the original papers (Schleper et al., 1995; Schleper et al., 1996) only poor information is given for the second species (*P. torridus*), their differentiation is not very clear. It is stated that *P. torridus* grows "significantly faster" than *P. oshimae*, contains no plasmids (which is however also true for some *P. oshimae* strains) and has a different DNA restriction pattern, although it resembles that of *P. oshimae*. Furthermore the 16S rRNA shows 3% difference within the first 250 positions. However, the sequence of *P. torridus* is still not available in the databases.

The third family, the Ferroplasmaceae, harbors one genus, *Ferroplasma*, with two species, *F. acidiphilum* type strain Y^T (DSM 12658^T;

Golyshina et al., 2000) and "*F. acidarmanus*" (Edwards et al., 2000). However, the latter is so far not validly described. The two species can be distinguished by the ability of "*F. acidarmanus*" to grow heterotrophically on yeast extract, whereas *F. acidiphilum* is unable to use yeast extract as sole energy source. Furthermore, the pH optima and range differ significantly (1.2 for "*F. acidarmanus*," range 0–2.5, and 1.7 for *F. acidiphilum*, range 1.3–2.2; Table 1). In 16S rRNA sequence analysis, no differences between both species were obtained.

Habitat

The first representative of the genus *Thermoplasma*, *T. acidophilum*, was isolated aerobically from a coal refuse pile in Indiana, in the United States (Darland et al., 1970). Further isolates were also obtained from self-heated smoldering coal refuse piles in the United States and from water samples at these locations (Belly et al., 1973; Brock, 1978). Although smoldering coal piles were obviously colonized within a short time after ignition (Belly et al., 1973; Brock, 1978) because of their anthropogenic origin, it appeared unlikely that they represent the primary habitat of the organism. A first natural habitat of *Thermoplasma* was reported in 1982, the occurrence of *Thermoplasma* in a Japanese hot spring (Ohba and Oshima, 1982). However, no further details had been published. A broad screening for *Thermoplasma* in numerous solfataric fields in Italy (Naples; Figs. 2–4; and Vulcano Island; Figs. 5 and 6), the United States (Yellowstone National Park, Wyoming), Iceland

Table 1. Differentiation of the species within the order Thermoplasmatales.

Properties	<i>Thermoplasma acidophilum</i>	<i>Thermoplasma volcanium</i>	<i>Picrophilus oshimae</i>	<i>Picrophilus torridus</i>	<i>Ferroplasma acidiphilum</i>	" <i>Ferroplasma acidarmanus</i> "
Morphology, size of cells	Pleomorphic, 0.2–5µm	Pleomorphic, 0.2–5µm	Irregular cocci, 1–1.5µm	Irregular cocci, 1–1.5µm	Pleomorphic, 1–3µm long, 0.3–1µm wide	Pleomorphic
Flagella	+	+	+	+	–	n.d.
Autotrophy	–	–	–	–	+ (needs vitamin solution)	+ and heterotrophic
Relation to oxygen	Facultatively aerobic	Facultatively aerobic	Aerobic	Aerobic	Aerobic	Aerobic

(Krisuvik), the Azores (Furnas), and Indonesia (Java) demonstrated that aerobic and anaerobic zones of continental volcanic areas are the natural habitat of these organisms (Segerer et al., 1988). In these studies, an additional isolate was obtained from a warm, acidic, tropical swamp in Java (Segerer et al., 1988). Although there was evidence that *Thermoplasma* can also thrive within marine hydrothermal systems, like the submarine solfatara field close to the beach on Vulcano Island, Italy (Segerer et al., 1988), no

Fig. 5. The island Vulcano, Italy, with the active solfataric area (in the center) and the Vulcanello (in the background).

isolates from deep-sea "black smoker" vents have been obtained so far (A. Segerer, unpublished observation).

Both *Picrophilus* strains were isolated from geothermal solfataric soils and springs in Hokkaido, northern Japan (Schleper et al., 1996). Therefore, they share in general the same biotopes as *Thermoplasma*, although their pH minima and optima are significantly lower. Since both *Picrophilus* species are inhibited by 0.2 M NaCl, they may be restricted to terrestrial geothermal environments.

Strains of *Ferroplasma* were isolated from a bioreactor, which was operated with gold-containing arsenopyrite/pyrite ore concentrate from Kazakhstan (Golyshina et al., 2000) and from a pyrite ore-body at Iron Mountain, California, United States (Edwards et al., 2000). In addition, 16S rRNA genes were detected in an acidic geothermal pool on the Caribbean island

Fig. 6. Sampling at the solfataric fields at Vulcano, Italy.

of Montserrat (Burton and Norris, 2000). Since both isolated organisms grow at temperatures around 37°C and have been isolated from highly distant locations, they may occur in many sulfidic ore-containing mines and heaps on earth.

Isolation

Enrichment

Several procedures to obtain *Thermoplasma* strains have been described. They can be enriched by aerobic incubation of samples in Darland's culture medium (see recipe below). Although low pH and high temperature are highly selective, overgrowth of rod-shaped, sporeforming, bacterial contaminants has been observed in many cases (Belly et al., 1973; Segerer et al., 1988), and good results were only obtained by adding appropriate antibiotics (e.g., vancomycin) to the cultures. Alternatively, the medium must be adjusted to pH 1 to prevent bacterial growth (Belly et al., 1973).

Alternatively, water samples were passed through a 0.45 µm filter followed by a passage through a 0.22 µm filter. Subsequent incubation of the latter in culture medium yielded pure cultures of *Thermoplasma* (Belly et al., 1973).

A highly selective and convenient procedure for the enrichment of *Thermoplasma* is incubation of samples in anaerobic media (Balch et al., 1979) in the presence of elemental sulfur (Segerer et al., 1988). Darland's medium, pH 2, was supplemented with 0.4% (w/v) of sulfur and incubated with an aliquot of the sample in rubber-stoppered serum bottles containing either a N₂ or N₂/CO₂ (80:20, v/v) atmosphere. The gas phase should be devoid of H₂ to prevent growth of facultatively or strictly anaerobic representatives of the order Sulfolobales, e.g., *Acidianus* or *Stygiolobus* strains. In enrichment cultures obtained by using this procedure, no contaminants were detected by light microscopy or plating (Searcy and Doyle, 1975a).

For the enrichment of *Picrophilus*, an aerobic growth medium described by Smith et al. (1975) was used (see below). Yeast extract (0.1%, w/v) and glucose (1%, w/v) served as carbon sources. Incubation was carried out at pH 1 at 60°C.

Strains of *Ferroplasma* were enriched in a modified 9K-medium (see below; Silverman and Lundgren, 1959; Golyshina et al., 2000) at pH 1.6–1.9 and at incubation temperatures between 28 and 30°C. Alternatively, enrichment in a medium according to Edwards et al. (1998) with a pH of 1 and at 37°C was described, using pyrite as energy source (Edwards et al., 2000). Since yeast extract is essential for the growth of both strains, this (0.02%, w/v) must be added to the culture media.

Isolation Procedures

For the isolation of *Thermoplasma*, Darland's culture medium (see below) is inoculated with samples (5% inoculum) and incubated at 59°C. *Thermoplasma* growth occurs within 2 days to 3 weeks. Isolation is achieved by subsequent plating, which is conveniently performed under aerobic conditions. Therefore, it is recommended that enriched cultures obtained by using the anaerobic enrichment procedure (see above) should be transferred once into aerobic liquid medium before plating. Alternatively, pure cultures can be obtained by thrice-repeated serial dilutions. However, the fastest and most secure isolation procedure is the separation by the use of optical tweezers (Huber et al., 1995).

Picrophilus strains were isolated by plating on 12.5% starch plates (pH 1) containing yeast extract and glucose. Colonies were obtained after 6 days at an incubation temperature of 60°C. Both strains of *Picrophilus* were isolated by serial dilutions. So far, nothing is published about growth on solidified media.

Ferroplasma has been isolated from a bioreactor and from an enrichment culture out of a pyrite ore-body by the use of serial dilutions. Growth on solidified media is so far not documented.

Identification

All representatives of the order are extremely acidophilic, growing optimally at $\text{pH} < 2$. The lack of a cell wall is characteristic for the members of the genera *Thermoplasma* and *Ferroplasma*, while *Picrophilus* possesses an outer S-layer. *Thermoplasma* and *Picrophilus* are further characterized by their thermophily, exhibiting temperature optima around 60°C . All organisms stain Gram negative and lack resting stages.

The diameter of *Thermoplasma* and *Ferroplasma* cells, ranging from 0.2 to roughly $5\ \mu\text{m}$ (Table 1), is highly variable. The same is true for the cell shape: filamentous, disc, and club (Fig. 7), and coccoid forms occur concomitantly in the same culture, making it difficult to ensure purity of the strain by microscopic investigations. Filamentous cells are especially abundant in the early exponential growth phase, while coccoid forms predominate in the stationary phase. Buds, about $0.3\ \mu\text{m}$ in width, are often associated with mother cells. In *Ferroplasma*, the buds appear tubular or vesicular in shape, tending to form septation annuli. The tubular extrusions range from 85 to 142 nm in diameter and up to $1\ \mu\text{m}$ in length (Golyshina et al., 2000). *Thermoplasma* and *Ferroplasma* cells are readily discernible from all other thermoacidophiles by the unique feature of lacking a true cell wall (Fig. 8). They

are surrounded by a single triple-layer membrane about 4–10 nm thick. *Thermoplasma* shows a pale yellowish-green fluorescence under ultraviolet (UV) radiation in the fluorescence microscope (Seegerer et al., 1988). Despite the lack of a cell wall, the cells are flagellated and motile (Black et al., 1979; Seegerer et al., 1988). Usually, monopolar, monotrichous flagellation is found, but sometimes multiflagellated cells also were observed (Seegerer et al., 1988). On solid media, colonies of *Thermoplasma* are usually small (about 0.5 mm in diameter) and are either colorless or brownish. As in the *Mycoplasmas*, fully grown colonies resemble a fried egg in shape (Darland et al., 1970; Belly et al., 1973).

Cells of *Picrophilus* are irregular cocci, 1 to $1.5\ \mu\text{m}$ in diameter (Table 1). In exponentially growing cultures, many cells are present in incompletely divided division forms of two or three individuals. Zones of low electron density were found after thin sectioning, resembling vacuoles, which were however not separated from the cytoplasm by a membrane. A 40-nm thick S-layer, which is situated on top of the cytoplasmic membrane, distinguishes *Picrophilus* from the other members of the Thermoplasmatales. The S-layer has a tetragonal symmetry (center-to-center distance about 20 nm) and consists of an outer dense and inner, almost empty stratum consisting of widely spaced pillars that anchor the surface layer in the membrane. No flagella or pili have been observed (Schleper et al., 1995).

All members of the Thermoplasmatales are resistant to cell wall inhibitors (like ampicillin or vancomycin) and to streptomycin. While *Picrophilus* is sensitive to chloramphenicol and

Fig. 7. Electron micrograph of cells of *Thermoplasma acidophilum* DSM 1728^T, Pt-shadowed. Bar $1\ \mu\text{m}$.

Fig. 8. Electron micrograph of a thin section of *Thermoplasma acidophilum*. Bar $1\ \mu\text{m}$. (The photograph was kindly provided by H. Engelhardt.)

novobiocin, the other organisms are resistant to these antibiotics.

Many molecular investigations were carried out with *Thermoplasma*, especially with *T. acidophilum*. It turned out that it contains a number of unique and characteristic chemical compounds. An unusual mannose-rich, 152-kDa glycoprotein is located in the cell membrane and is thought to form a hydroskeleton via a network of sugar residues surrounding the cell, thus contributing to the remarkable rigidity of the membrane (Yang and Haug, 1979). The membrane lipids contain predominantly acyclic, mono- and bi- pentacyclic C₄₀ biphytanyl diglycerol tetraethers along with small amounts of C₂₀ phytanyl glycerol diethers (Langworthy, 1977; Langworthy, 1985; Langworthy et al., 1982; Langworthy and Pond, 1986). The structure of a polar tetraether lipid was fully established and shown to be a lipoglycan (MW 5,300), consisting of 24 mannosyl residues and one glucosyl residue bound to a diglyceryltetraether (Mayberry-Carson et al., 1974; Smith, 1980). Several novel neutral glycolipids, consisting of caldarchaeol (dibiphytanyl-diglycerol tetraethers) and monosaccharide residues (gulose and glucose) on one side or both sides of the core lipids, were described recently for *T. acidophilum* (Uda et al., 1999). *Picrophilus* has similar lipids, with the exception that a β -glycosyl residue is present in the major lipid component. In contrast, *Ferroplasma* contains no tetraethers. The main phospholipid is archaetidyl glycerol. Furthermore, archaetic acid and dimers of both ether lipids were found in small amounts (Schleper et al., 1995).

The DNA-dependent RNA polymerase of *Thermoplasma* consists of seven subunits and is resistant to rifampicin, streptolydigin and α -amanitin (Sturm et al., 1980). In the corresponding enzyme of *Picrophilus*, several components were absent (e.g., A" and E) and the enzyme does not crossreact in immunodiffusion assays with antibodies against the *Thermoplasma* enzyme (Schleper et al., 1995). The respiratory chain of *Thermoplasma* contains at least one b-type cytochrome (Belly et al., 1973; Holländer, 1978; Searcy and Whatley, 1982) and several quinones (Holländer et al., 1977; Collins and Langworthy, 1983). Among the quinones, a characteristic compound called "thermoplasmaquinone" was found, which was not detected in other Archaea. In addition, menaquinone and methionaquinone are present (Shimada et al., 2001). Coenzyme F₄₂₀ is present in about 1% of the amount typical for methanogens (Lin and White, 1986). The DNA is associated with a small basic histone called "Hta" that exhibits partial amino acid sequence homology to the HU-1 protein of *Escherichia coli* and to the calf thymus histones H3 and H2A

(Searcy, 1975a; Searcy and DeLange, 1980; DeLange et al., 1981). *Thermoplasma acidophilum* possesses a protein that resembles the human ubiquitin (Wolf et al., 1993). Furthermore, it contains proteasomes, which function as threonine proteases in ATP-dependent proteolysis (Seemüller et al., 1995). Structural investigations on the thermosome, which represents the archaeal chaperonin, were carried out by electron cryo-microscopy and by high resolution analysis (2.6 Å) of protein crystals (Nitsch et al., 1997; Ditzel et al., 1998). Based on these results, the molecule is composed of two stacked eight-membered rings of alternating α - and β -subunits. Studies on the mechanism of its ATPase activity revealed that the thermosome had unique allosteric properties (Gutsche et al., 2000).

For *Picrophilus*, bioenergetic studies with liposomes indicate an intrinsic instability of the cytoplasmic membrane at higher pH values, resulting in a loss of viability and cell integrity above pH 4 (van de Vossenberg et al., 1998).

Cultivation

Medium for *Thermoplasma* Species

Darland's medium is suitable for the growth of all strains of *Thermoplasma*.

Darland's Medium (Darland et al., 1970)

KH ₂ PO ₄	3.00 g
MgSO ₄ · 7H ₂ O	1.02 g
CaCl ₂ · 2H ₂ O	0.25 g
(NH ₄) ₂ SO ₄	0.20 g
Yeast extract	1.00 g
Glucose · H ₂ O	10.0 g

The mineral base of the medium is dissolved in one liter of double-distilled water and the pH is adjusted to around 2 with 10% (v/v) H₂SO₄.

For aerobic cultivation, 30-ml aliquots are distributed into 100-ml Erlenmeyer flasks equipped with an air cooler (e.g., a 1-ml pipette tightly fitted through a rubber stopper) and autoclaved. Yeast extract, glucose, and (if necessary) meat extract are added separately from sterile stock solutions. Reduction of the glucose content to 0.5% (w/v) does not significantly affect growth and cell yield. For reasons of convenience, we prepare a stock mixture of 30% (w/v) glucose and 6% (w/v) yeast extract (plus, if desired, 3% [w/v] meat extract), which is sterilized by passage through a 0.2- μ m filter membrane. From this stock, 0.5-ml are added to each 30 ml of mineral base medium.

For anaerobic cultivation of *Thermoplasma* strains, the medium must be supplemented with about 0.4% (w/v) elemental sulfur. It is distributed as 15-ml aliquots into 100-ml serum bottles. The atmosphere (~150 kPa) may consist of N₂, N₂/CO₂ (80:20 v/v), or H₂/CO₂ (80:20 v/v). Serum bottles containing elemental sulfur must be sterilized by Tyndall's fractional sterilization procedure.

Aerobic and anaerobic media for the strains of *T. volcanium* group 3 (see "Identification") should be supplemented with 0.025–0.05% (w/v) meat extract in addition to yeast extract and glucose.

Medium for *Picrophilus* Species

This medium was originally described by Smith et al. (1975) according to E. A. Freundt for the cultivation of *Thermoplasma acidophilum* (Schleper et al., 1995). It is in principle similar to Darland's medium, with the exception of the absence of KH_2PO_4 .

$(\text{NH}_4)_2\text{SO}_4$	0.20 g
$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	0.50 g
$\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$	0.25 g
Yeast extract	1.00 g

The pH is adjusted to around 2 with 10 N H_2SO_4 . After autoclaving, glucose is added to a final concentration of 1%.

MEDIUM FOR *FERROPLASMA* SPECIES A modified 9K medium (Silverman and Lundgren, 1959) is used for the cultivation of *Ferroplasma* (Golyshina et al., 2000).

$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	0.40 g
$(\text{NH}_4)_2\text{SO}_4$	0.20 g
KCl	0.10 g
K_2HPO_4	0.10 g
$\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$	25.0 g
Yeast extract	0.20 g
Trace elements	1.0 ml

The pH is adjusted to 1.7 with 10% (v/v) H_2SO_4 . Trace elements are described by Segerer and Stetter (1992b). For the growth of both *Ferroplasma* strains, ferrous sulfide can be replaced by pyrite.

Cultivation on Plates

For growth on solidified media, best results are obtained for members of the Thermoplasmatales using 10–12% starch (e.g., Stärke Gel, Serva). Only poor results were obtained by plating *Thermoplasma* spp. onto agar or Gelrite plates (Searcy and Doyle, 1975a). It is recommended to adjust the pH to about 3 just before pouring the plates. High and reproducible yields (plating efficiency ~90 to 100%) were obtained by incubating the plates in a pressure cylinder (Balch et al., 1979) microaerobically, in a humid atmosphere consisting of roughly 60% air and 40% CO_2 (v/v). Small, colorless to brownish colonies showing the “fried egg” appearance typical of *Thermoplasma* emerged within 7 or more days.

Cultivation Conditions

Strains of *Thermoplasma* (*Picrophilus* and *Ferroplasma*) can be cultivated in a wide variety of glass bottles and fermentors. Special attention has to be paid to the construction of fermentors because of the high corrosivity of the medium due to the low pH, elevated temperature, and (in case of anaerobic cultivation) high amounts of H_2S produced during growth. Therefore, only

fermentors containing high-quality steel are recommended.

All *Thermoplasma* strains investigated thus far are best grown at 57–59°C and at around pH 2, whereas for *Picrophilus*, the optimal pH is 0.7. Optimal growth for *Ferroplasma* strains occurs between pH 1.2 (“*F. acidarmanus*”) and 1.7 (*F. acidiphilum*), with temperature optima of 40 and 35°C, respectively.

Preservation

Cultures of *Thermoplasma* are significantly more resistant to storage procedures when grown anaerobically. The reason for this phenomenon, which is also observed with *Acidianus* spp. (Segerer et al., 1986a), is unknown. Adjustment to pH ~5 with sterile CaCO_3 prior to storage has a further positive influence on long-term viability, presumably because *Thermoplasma* actively maintains an internal pH of about 5 (Searcy, 1976). Possible damage to cells during storage caused by the penetration of acids is thus avoided. Therefore, for storage, the use of anaerobically grown cultures at pH ~5 and 4°C is recommended. Although viability of such cultures is sufficient even after 12 months of storage, maintenance transfer every 2–3 months is advised. Best results for long-term storage are achieved in culture media containing 5% DMSO (dimethyl sulfoxide) and storage in the gas phase over liquid nitrogen (around –140°C; H. Huber and K. O. Stetter, unpublished observation).

Viable stock cultures for *Picrophilus* can be obtained by suspending cells in basal salt medium (pH 4.5) containing 20% glycerol. These suspensions can be kept at –70°C. Neutralization of the culture medium for short-term storage is not recommended because *Picrophilus* lyses above pH 5 (Schleper et al., 1995).

Nothing is stated in the original papers on preservation results for *Ferroplasma* (Golyshina et al., 2000; Edwards et al., 2000). However, it should be possible to store these strains in fresh medium supplemented with 5% DMSO over liquid nitrogen.

Physiology

The members of the genus *Thermoplasma* are obligately heterotrophic, facultatively anaerobic thermoacidophiles that require the presence of yeast extract or similar extracts for growth. At growth-limiting concentrations of yeast extract, the carbohydrates sucrose, glucose, mannose, galactose, and fructose were found to stimulate growth significantly (Belly et al., 1973; Brock, 1978). However, no growth occurs on sugars

alone or on peptone, tryptone, casamino acids, various amino acids, and alcohols. As shown by Smith et al. (1975), the growth factor(s) present in yeast extract is most likely a basic oligopeptide consisting of 8–10 amino acids. Although *Thermoplasma* has an absolute requirement for yeast extract (Langworthy and Smith, 1989), this organism also grows in the presence of meat extract or bacterial extracts (Segerer et al., 1988), suggesting that the same or similar growth factors are present in those extracts. Therefore, the nutrition of *Thermoplasma* in its natural habitat is most likely based on the products of decomposing cells of organisms sharing the biotope, e.g., *Acidianus brierleyi* (Brierley and Brierley, 1973; Segerer et al., 1986a), *Bacillus acidocaldarius* (Darland and Brock, 1971), *Cyanidium caldarium* (Geitler and Ruttner, 1936), or *Dactylaria gallopava* (Tansey and Brock, 1973). Additionally, *Thermoplasma* was also found to grow poorly on an extract of coal refuse material (Bohloul and Brock, 1974). However, it is not clear from this study whether the coal itself provides all necessary nutrients or not.

Glucose degradation was investigated in *T. acidophilum*. Although contradictory results were obtained, degradation appears to take place via a modified Entner-Doudoroff pathway involving nonphosphorylated intermediates, rather than via the pentose phosphate pathway or glycolysis (Searcy and Whatley, 1984; Budgen and Danson, 1986). By using D-[U-¹⁴C]-glucose as tracer, CO₂ and acetic acid were detected as metabolic products, in addition to the respiration of cell extracts by key intermediates of the citric acid cycle and the presence of the enzymes malate dehydrogenase and citrate synthase. This suggests the operation of a Krebs cycle (Searcy and Whatley, 1984; Grossebüter and Görisch, 1985; Grossebüter et al., 1986).

Thermoplasma spp. grow as facultative anaerobes on molecular sulfur by sulfur respiration, forming large amounts of H₂S (Seegerer et al., 1986b; Segerer et al., 1988). This feature was in the beginning unknown, and the organism was considered to be a strict aerobe (Darland et al., 1970; Langworthy and Smith, 1989). Low cell densities are obtained when the cells are grown anaerobically without sulfur, indicating the presence of further unknown electron acceptor(s). Sulfur is not a prerequisite for aerobic cultivation. When *Thermoplasma* was grown aerobically in the presence of sulfur, no formation of H₂SO₄ was found (Brock, 1978; Segerer et al., 1988), a feature typical for members of the genus *Acidianus* (Seegerer et al., 1986a). In addition, no growth occurs on ferrous iron.

The growth temperatures range from about 45–67°C for *T. acidophilum* and from about 33–67°C for *T. volcanium*. The optimum growth

temperature is around 59°C. Both species grow within a pH range of 0.5–4, with an optimum around pH 2 (Table 1), but growth is very slow at both extremes.

Cells lyse at neutral pH, indicating that *Thermoplasma* has an absolute requirement for protons. They cannot be replaced by other monovalent or divalent ions. Nevertheless, the internal pH is near neutrality (Hsung and Haug, 1975; Searcy, 1976). The cells do not lyse in distilled water or during heating up to 100°C. However, cells are rapidly disintegrated in the presence of sodium dodecyl sulfate (SDS).

The representatives of *Picrophilus* are obligately aerobic heterotrophs. They cannot grow by fermentation or by chemolithotrophic pathways, like sulfur respiration. Yeast extract (0.1–0.5%) serves as an energy source, yielding cell densities up to 5×10^8 cells/ml. A slight stimulation is achieved by addition of 1% glucose, sucrose or lactose. No growth occurs on these sugars alone, on starch, or on casamino acids. Growth is inhibited by the addition of relatively small amounts of NaCl (0.2 M). *Picrophilus* strains are thermophilic, exhibiting temperature optima around 60°C. No growth occurs at 40°C and below and at 67°C or above. The optimal pH is 0.7, and no growth is obtained at pH 3.5 or above, indicating that the organisms are “hyperacidophilic.” Even at pH 0, cell division occurs (Schleper et al., 1995).

In contrast to the other genera, *Ferroplasma* harbors also chemolithoautotrophic organisms. *Ferroplasma acidophilum* is able to use CO₂ as a carbon source and ferrous iron or pyrite as an energy source. Ferric ion (Fe³⁺) is the end product of the oxidation. In addition, Mn²⁺ can be oxidized. No growth occurs on other sulfidic ores or reduced sulfur compounds like elemental sulfur, thiosulfate or tetrathionate. No growth could be observed on organic substrates, although the addition of yeast extract is essential for cell propagation (Golyshina et al., 2000). It was detected that yeast extract can be replaced by a vitamin solution. “*Ferroplasma acidarmanus*” is able to grow in addition heterotrophically on yeast extract as sole energy source. It grows between pH 0 and 2.5, with an optimum at 1.2 (*F. acidophilum* pH 1.7–2.2, optimum 1.7; Edwards et al., 2000). Both organisms are mesophiles with a temperature optimum around 37°C (Table 1).

Genetics

The whole genomes of *Thermoplasma acidophilum* and *Thermoplasma volcanium* were sequenced recently (Ruepp et al., 2000; Kawashima et al., 2000). The genomes have sizes of only 1,565 kb and 1,585 kb, respectively, being some of

the smallest among free-living organisms. In *T. acidophilum*, 1,509 ORFs were identified, and about 16% have so far no database match. Each of the three ribosomal RNA genes is present in one copy, but the three genes are dispersed in the genome. Analyses of the data revealed that *T. acidophilum* is a typical member of the Euryarchaeota, although the highest number of ORFs (17%) was most similar to proteins of *Sulfolobus solfataricus*. The complete sequence also showed that *Thermoplasma acidophilum* is a typical Archaeon and therefore most likely not a direct ancestor of the eukaryotic cytoplasm (Ruepp et al., 2000). In general, it turned out that two classes of genes can be distinguished: the “housekeeping” genes reflect generally the phylogenetic origin, while the “lifestyle” genes (mostly genes related to metabolism) are influenced by the specific environment (Ruepp et al., 2000). In *T. volcanium*, 1,524 genes were identified. The main goal of this genome sequencing was the investigation of a correlation between higher growth temperature and genomic organization (Kawashima et al., 2000).

Ecology

Representatives of the Thermoplasmatales thrive in highly acidic biotopes, covering temperatures from 20 up to 60°C. While *Thermoplasma* and *Picrophilus* are typical inhabitants of heated solfataric areas, recent results document that *Ferroplasma* seems to be widely distributed in pyrite-dominated ore-containing habitats at temperatures around 37°C (Bond et al., 2000; Vásquez et al., 1999). So far, these biotopes were thought to be dominated by bacteria, like *Thiobacillus ferrooxidans* (now *Acidithiobacillus ferrooxidans*; Kelly and Wood, 2000), *Leptospirillum ferrooxidans*, or *Acidiphilum*. However, especially for lower pH regions in mines, ore bodies, or drainage waters, *Ferroplasma* seems to be more important than the other organisms.

The Order Halobacteriales

AHARON OREN

Introduction

Halophilic Archaea of the order *Halobacteriales* are found in hypersaline environments in which salt concentrations exceed 150–200 g/liter. They inhabit salt lakes such as the Great Salt Lake, Utah, the Dead Sea, and other hypersaline water bodies such as the crystallizer ponds of solar salt-erns in which sea water is evaporated for the production of salt. Additional habitats in which these halophilic Archaea often develop include salted fish and hides preserved by treatment with salt. They also occur in certain fermented food products in which molar concentrations of NaCl are added as part of the manufacturing process, such as Thai fish sauce.

Microbial deterioration of salted hides and salted fish by members of the *Halobacteriales* is clearly visible by the pink-red color of the developing colonies (Clayton and Gibbs, 1927; Harrison and Kennedy, 1922; Lochhead, 1934; Shewan, 1971; Vreeland et al., 1998a). Many of the early studies on the red halophilic Archaea were initiated in an attempt to understand the cause of the damage to fish and hides treated with salt for their preservation. The account by Klebahn, 1919 on the bacteria causing the red discoloration of salted cod probably presents the first accurate description of halobacteria, at the time designated as “*Bacillus halobius ruber*.” That study was followed by the isolation of “*Pseudomonas salinaria*” from the red discoloration of cured codfish (Harrison and Kennedy, 1922). This culture is now lost, but the organism is probably very similar to later isolates known as *Halobacterium salinarum*. Another classic early study on the red halophilic bacteria that grow on salted fish is that of Petter, 1931. The phenomenon of bacterial degradation of salted hides was documented by Lochhead, 1934. During the 1930s also the first studies appeared of the microbiology of solar salterns and salt lakes, describing the importance of red halophilic bacteria in these ecosystems (Baas-Becking, 1931; Hof, 1935). Many of the early studies on the *Halobacteriales* were summarized in Larsen’s classic essay on “the halobacteria’s confusion to

biology” (Larsen, 1973). Tindall, 1992 presented an in-depth discussion on the properties, nomenclature, and taxonomic affiliations of some of the early isolates.

The mode of adaptation of the *Halobacteriales* to life at salt concentrations at or near NaCl saturation has been the subject of in-depth studies. In contrast to most other halophilic or halotolerant microorganisms that keep intracellular ionic concentrations low, cells of the halophilic Archaea of the order *Halobacteriales* contain molar concentrations of ions, especially K^+ and Cl^- , within the cells (Christian and Waltho, 1962; Matheson et al., 1976; Oren, 1999a; Pérez-Fillol and Rodriguez-Valera, 1986). The maintenance of high intracellular salt concentrations requires unique adaptations of the enzymatic machinery to be able to function in the presence of high salt, adaptations that make the cells of most species strictly dependent on the continuous presence of high salt concentrations for the maintenance of structural integrity and viability (Dennis and Shimmin, 1997; Ebel et al., 1999; Eisenberg, 1995; Eisenberg and Wachtel, 1987; Eisenberg et al., 1992; Lanyi, 1974).

Much of the interest of the scientific community in the genus *Halobacterium* and other representatives of the *Halobacteriales* was triggered by the discovery of the retinal pigments, bacteriorhodopsin and halorhodopsin. The structure of bacteriorhodopsin and its function as an outward proton pump were disclosed in the early 1970s (Danon and Stoeckenius, 1974; Oesterhelt and Stoeckenius, 1971). The function of halorhodopsin as an inward chloride pump was recognized in 1982 (Schobert and Lanyi, 1982). Both proteins enable the direct use of light energy by the cells for energy transduction. Additional retinal proteins serve as light sensors to direct the phototactic machinery of cells of motile species to an optimal light environment (Bogomolni and Spudich, 1982; Spudich and Bogomolni, 1988; Spudich et al., 1995). The retinal pigments rapidly became popular models for in-depth biochemical and biophysical studies (Lanyi and Váró 1995; Oesterhelt, 1995). In addition, the unique properties of these pig-

ments also present promising features for future biotechnological applications (Birge, 1995; Chen and Birge, 1993; Hong, 1986; Oesterhelt et al., 1991).

Different aspects of the biology of the *Halobacteriales* have been reviewed in the past. In addition to review papers cited in the sections relating to specific subjects, much useful information can be found in reviews by Bayley and Morton, 1978; Grant and Ross, 1986; Kushner, 1985; Larsen, 1962; Tindall and Trüper, 1986; Trüper and Galinski, 1986; the reviews on physiology and metabolism by Dundas, 1977 and by Hochstein, 1988 and on the genetics of the group by Pfeifer, 1988; the ecological survey by Oren, 1994a; the taxonomic treatment in *Bergey's Manual* (Grant and Larsen, 1989); and the treatises on the group in the earlier editions of *The Prokaryotes* (Larsen, 1981; Tindall, 1992).

Phylogeny

The question "Are extreme halophiles actually 'bacteria'?" (Magrum et al., 1978) had to be answered negatively when it was recognized in the late 1970s that *Halobacterium salinarum* and related halophiles belong to the newly recognized domain Archaea. This finding again increased the interest in the *Halobacteriales*, as of all archaeal groups, they are the most easily handled in the laboratory (Shand and Perez, 1999a).

The *Halobacteriales* (Grant and Larsen, 1989) form a branch within the Euryarchaeota, branching off close to the *Methanomicrobiales*/*Methanosarcinales*. At the time of writing (June 1999) a single family was recognized within the order *Halobacteriales*: the *Halobacteriaceae*. Presently this family is divided into 14 genera with 35 validly described species (Table 1).

Table 1. The genera and species within the order Halobacteriales.

Family	Genus	Species
Halobacteriaceae	<i>Halobacterium</i> ^T	<i>Halobacterium salinarum</i> ^T
	<i>Halobaculum</i>	<i>Halobaculum gomorense</i> ^T
	<i>Halorubrum</i>	<i>Halorubrum saccharovororum</i> ^T
		<i>Halorubrum sodomense</i>
		<i>Halorubrum lacusprofundi</i>
		<i>Halorubrum coriense</i>
		<i>Halorubrum distributum</i>
		<i>Halorubrum vacuolatum</i>
		<i>Halorubrum trapanicum</i>

		<i>Natronorubrum tibetense</i>

^T = type genus of the family or type species of the genus.

Fig. 1. Phylogenetic tree of the *Halobacteriaceae*, prepared by T.J. McGenity (Department of Biological Sciences, University of Essex, U.K.). Distances were calculated by the method of Jukes and Cantor, 1969, and the tree was produced by the method of Fitch and Margoliash, 1967. Bootstrap percentages above 75% are shown at the nodes.

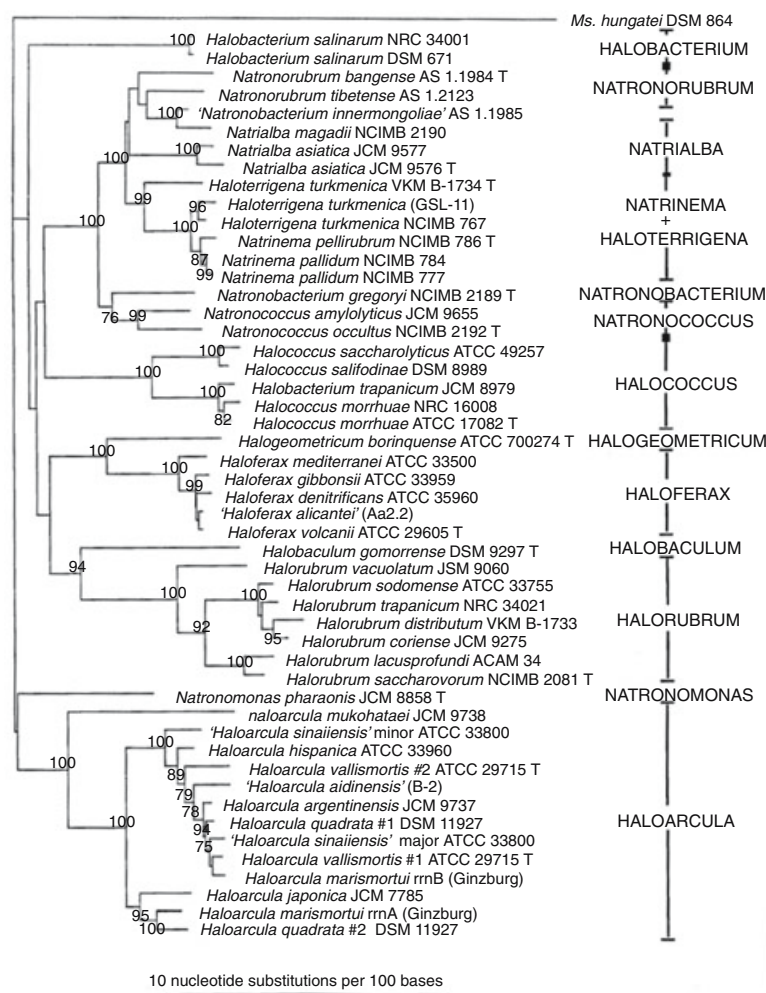

Figure 1 presents a phylogenetic tree of the family, based on 16S rDNA sequence comparisons.

Taxonomy

The order *Halobacteriales* contains a variety of morphological types, from rods and cocci to flat extremely pleomorphic types (Mullakhanbhai and Larsen, 1975), perfectly square flat cells (Kessel and Cohen, 1982; Oren, 1999b; Oren et al., 1996c; Parkes and Walsby, 1981; Romanenko, 1981; Stoeckenius, 1981; Walsby, 1980), and triangular and trapezoid cells such as displayed by *Haloarcula japonica* (Hama-moto et al., 1988; Horikoshi et al., 1993; Takashina et al., 1990). The micrographs shown in Figs. 2–4 present a selection of the morphological types encountered within the group.

Classification and identification of the genera and species belonging to the order *Halobacteriales*, family *Halobacteriaceae* are currently based on a polyphasic approach (Oren et al., 1997a),

involving properties such as cell morphology, growth characteristics, chemotaxonomical traits (notably the presence or absence of specific polar lipids), and nucleic acid sequence data. The properties of the validly described genera and species are summarized in Tables 2–6. More detailed information can be found in the individual species descriptions (see the literature citations at the end of each table). Useful taxonomic information can be found online, as well (Euzéby, 1999).

In recent years the comparison of 16S rDNA sequences has led to a new classification, including the creation of a number of new genera, the splitting of existing genera, and in a number of cases also the unification into one genus of two species classified earlier in separate genera (see e.g., Kamekura, 1998; Kamekura, 1999; Kamekura and Seno, 1993). Comparison of 16S rRNA nucleotide sequences led to the insight that the alkaliphiles do not form a defined phylogenetic group, but many alkaliphilic species are interspersed between their neutrophilic relatives

Fig. 2. Some representatives of the *Halobacteriales*: *Halobacterium salinarum* (a), *Natronobacterium gregoryi* (b), *Halorubrum lacusprofundi* (c), *Natronomonas pharaonis* (d), *Haloarcula japonica* (e), Walsby's square bacterium (f), *Halogeometricum borinquense* (g), and *Natronococcus occultus* (h). Phase contrast. Gas vesicles are visible in (a) and (g). Reproduced from Horne and Pfeifer, 1989, Tindall et al., 1984, Franzmann et al., 1988, Soliman and Trüper, 1982, Horikoshi et al., 1993, Stoeckenius, 1981, Mwatha and Grant, 1993, and Tindall et al., 1984, respectively, with permission from the publishers.

Fig. 3. Electron micrographs of *Halobacterium salinarum*: negatively stained preparations, showing flagella (a) and gas vesicles (b), and thin sections (c, d), showing details of the cell envelope structure and the arrangement of the nuclear material. Reproduced from Alam and Oesterhelt, 1984a, Houwink, 1956, Usukura et al., 1980, and Cho et al., 1967, respectively, with permission from the publishers.

Fig. 4. Electron micrographs of different representatives of the *Halobacteriales*: thin sections of *Haloferax volcanii* (a) and *Haloferax mediterranei* (containing large amounts of poly- β -hydroxyalkanoate) (b), transmission (c) and scanning electron micrographs (d) of *Halococcus salifodinae*, and negatively stained cells of Walsby's square bacterium (e). Reproduced from Mullakhanbhai and Larsen, 1975; Rodriguez-Valera and Lillo, 1992b; Denner et al., 1994; and Parkes and Walsby, 1981, respectively, with permission from the publishers.

in the phylogenetic tree. The present-day emphasis on 16S-rRNA sequence data for the determination of the phylogenetic position of the different members of the halophilic Archaea has reduced the relative importance of the polar lipid composition, as certain diagnostic glycolipids may be found in more than one genus, and members of certain genera may contain different glycolipids (for an in-depth discussion see Kamekura, 1999). Figure 1 presents a phylogenetic tree of the *Halobacteriaceae*, based on 16S rDNA sequence comparisons. Also the 23S rRNA genes have been used in some taxonomic studies, and the analysis of the available data suggested that the halobacterial genes diverged over a relatively short time (Lodwick et al., 1994).

Lost and contaminated strains, as well as improper strain designations, have caused much confusion in the past. Since the in-depth discussion and critical assessment of strain histories and identities by Tindall, 1992, many of the old controversies have been resolved. However, considerable confusion still exists on the true nature of certain strains (see e.g., the notes to Table 2). Thus, different strains designated *Halorubrum saccharovorum* possess different glycolipids (Tindall, 1990b). The importance of the use of type strains in taxonomic and other (e.g. biochemical and genetic) studies should be stressed here once more. In case of doubt, molecular biological techniques now enable easy tests for the authenticity of the strains used. Random amplified polymorphic DNA analysis (RAPD), using oligonucleotide probes of arbitrary sequence, was used to compare closely related strains (Martinez-Murcia and Rodriguez-Valera, 1994) and was found to be a powerful tool to sort out

problems of strain identity (Martinez-Murcia et al., 1995a). Another useful way to compare strains and resolve questions about their authenticity is to determine protein profiles with SDS polyacrylamide electrophoresis gels (Hesselberg and Vreeland, 1995).

A number of species *incertae sedis* exist that are awaiting to be described either as new species or as representatives of recognized taxa: "*Haloarcula aidinensis*" (Peijin and Yi, 1996; Peijin et al., 1995; Yi et al., 1995), "*Haloarcula californiae*" (Javor et al., 1982), "*Natronobacterium innermongoliae*" (Tian et al., 1997), and "*Haloferax alicantei*" (Holmes et al., 1997). There are also yet uncultured types, known either by their distinct morphology or from 16S rDNA sequences amplified from brine samples. Thus, the gas vesicle containing square non-motile Archaea first described by Walsby, 1980 and since observed and studied in many hypersaline environments (Guixa-Boixareu et al., 1996; Kessel and Cohen, 1982; Oren, 1999b; Oren et al., 1996c; Parkes and Walsby, 1981; Romanenko, 1981; Stoeckenius, 1981; Torrella, 1986) still defy the microbiologists' attempts to culture them. They probably contain S-DGD-1 as their major glycolipid (Oren et al., 1996c) and are therefore probably unrelated to the motile square isolate 801030/1 obtained from the same brine pool in the Sinai peninsula (Egypt) in which the gas vesicles containing square bacteria were first observed (Alam et al., 1984). This strain was recently described as a new species of the genus *Haloarcula*, *Haloarcula quadrata* (Oren et al., 1999). Random amplification of 16S rDNA sequences from saltern crystallizer ponds in Spain and Israel consistently yielded one phylogroup appearing at the highest frequency. This

Data were derived from the original species descriptions and from Grant and Larsen (1989) and Tindall (1992). Data on anaerobic growth on arginine were derived in part from Oren (1994b) and Oren and Litchfield (1999).

+: all strains tested positive; -: all strains tested negative; ±: weak reaction; d: some strains positive; NR: not reported.
¹Type species of the genus.
^aThe species *Halobacterium salinarum* includes strains formerly named *Halobacterium halobium* and *Halobacterium cutirubrum* (Ventosa and Oren, 1996). For additional properties of the group see Colwell et al. (1979).
^bFranzmann et al. (1988) reported a positive reaction.
^cPositive growth on single carbon sources may in certain cases require low concentrations of additional growth factors (to be satisfied e.g., by addition of 0.005% yeast extract).
^dFranzmann et al. (1988) reported a negative reaction.
^eControversial data have been published on the structure of the sulfated diglycosyl diether lipids present in different species of *Halorubrum* (Kamekura, 1998; Lanzotti et al. 1998).
^fZvyagintseva et al. (1996) proposed strain VKM B-1739 as the new type strain of *Halorubrum distributum* to replace VKM B-1733. However, no compelling reasons for the change were brought forward, and therefore strain VKM B-1733 should remain the type strain of the species (Oren et al., 1997b).
^gConsiderable confusion has existed in the past on strain identities and the assignment of a type strain. For details see Tindall (1992) and Grant et al. (1998a).

+; all strains tested positive; -: all strains tested negative; ±: some strains positive; NR: not reported.

^aType species of the genus.

^bIn view of the different glycolipid content, lack of the characteristic *Haloarcula* signature bases in the 16S rDNA sequence, and other properties in which *Haloarcula mukohataei* differs from the other representatives of the genus *Haloarcula*, reclassification in another, newly to be created, genus may be desirable (Kamekura 1999).

^cConflicting reports: Soliman and Trüper (1982) reported a negative reaction, while Tindall et al. (1984) stated a positive reaction.

^dPositive growth on single carbon sources may in certain cases require low concentrations of additional growth factors (to be satisfied e.g., by addition of 0.005% yeast extract).

^eConflicting reports exist.

^f*Haloarcula* species typically have more than one heterologous 16S rRNA: two were identified in *Haloarcula marismortui* (Mylvaganam and Dennis, 1992), *Haloarcula argentinensis* possesses at least four genes, and *Haloarcula mukohataei* contains at least three different genes (Thara et al., 1997).

Species incertae sedis classified within the genus *Haloarcula* are:

- Haloarcula sinaiensis*, isolated from a brine pool in the Sinai peninsula, Egypt (Javor et al., 1982). The strain has been deposited as ATCC 33800 and NCIMB 2268, and its 16S rDNA gene sequences are D14129 (major gene) and D14130 (minor gene).
- Haloarcula californiae*, isolated from Guerrero Negro, Baja California, Mexico (Javor et al., 1982). The strain has been deposited as ATCC 33799 and NCIMB 2267.
- Haloarcula aidinensis*, isolated from a salt lake in Xinyang, China (Peijin and Yi, 1996; Peijin et al., 1994; Yi et al., 1995), deposited as AS 1.2042, with 16S rDNA sequence AB000563.

phylogeny has a low similarity to the 16S rDNA sequences of any of the genera defined thus far and is only remotely related to the genus *Haloferrax*, its closest relative (Benlloch et al., 1995; Benlloch et al., 1996; Rodríguez-Valera et al., 1999). The organism harboring this 16S rDNA gene still awaits isolation.

Sensitivity to antibiotics and other antibacterial substances

Sensitivity to antibiotics and other antibacterial substances is often used in taxonomic studies in which strains are characterized or compared. Being Archaea, members of the *Halobacteriales* typically are resistant to such Bacteria-specific antibiotics as penicillin, ampicillin, cycloserine, kanamycin, neomycin, polymyxin, and streptomycin (Bonelo et al., 1984a; Hilpert et al., 1981; Pecher and Böck, 1981). Regarding their sensitivity to chloramphenicol, conflicting information exists: although most reports state resistance to chloramphenicol, Pecher and Böck, 1981 found inhibition already at 31 µg/ml, and they also reported some sensitivity to tetracycline and aureomycin (both with a minimal inhibitory concentration of 62 µg/ml). *Halobacterium salinarum* was reported to be inhibited by chloramphenicol and erythromycin at concentrations > 100 µg/ml and to be susceptible to tetracycline at > 8 µg/ml (Chow and Mark, 1980). Sensitivity to high concentrations of chloramphenicol (minimal inhibitory concentrations up to 750–1500 µg/ml in most species tested and 141 µg/ml in *Haloferax mediterranei*) was also reported by Bonelo et al., 1984a. Some species may be inhibited by high concentrations (>150 µg/ml) of erythromycin (Bonelo et al., 1984a; Pecher and Böck, 1981).

Most halophilic Archaea are sensitive to novobiocin and bacitracin. Novobiocin is a DNA gyrase inhibitor (Holmes and Dyall Smith, 1991; Sioud et al., 1988) and acts on the same target in the Archaea as in sensitive Bacteria. *Halococcus saccharolyticus* presents a notable exception, being resistant to novobiocin inhibition (Montero et al., 1989), but *Halococcus morrhuae* is sensitive (Hunter and Millar, 1980). Bacitracin inhibits incorporation of the high-molecular-weight saccharide into the cell wall glycoprotein of non-cocoid halophilic Archaea (Wieland et al., 1980; Wieland et al., 1982) and may also inhibit lipid biosynthesis in these organisms (Basinger and Oliver, 1979).

Members of the *Halobacteriales* were found to be sensitive to a number of additional antibiotics and other antibacterial compounds:

- Anisomycin, a protein synthesis inhibitor of eukaryal ribosomes, also inhibits protein synthesis of all members of the *Halobacteriales* tested,

Fig. 5. Structure of the antibiotic haloquinone.

both *in vivo* and *in vitro* (Pecher and Böck, 1981).

- Cerulenin, a potent inhibitor of the synthesis of the straight-chain fatty acids by the fatty acid synthetase complex, inhibits *Halobacterium salinarum* (and possibly other members of the order as well) (Dees and Oliver, 1977). This finding suggests that the production of straight-chain fatty acids is essential even in an organism possessing archaeal type lipids. It is now known that fatty acids are used to acylate certain membrane proteins (Pugh and Kates, 1994).

- *Halobacterium salinarum* was found sensitive to haloquinone, an antibiotic substance produced by *Streptomyces venezuelae* subsp. *xanthophaeus* (Fig. 5), affecting DNA synthesis (Ewersmeyer-Wenk et al., 1981).

- Rifampicin was reported to be inhibitory to many members of the *Halobacteriaceae* (Bonelo et al., 1984a; Hilpert et al., 1981; Pecher and Böck, 1981). The target of rifampicin action in the halophilic Archaea is probably not the DNA-dependent RNA polymerase, but the cell membrane upon which it exerts a detergent effect, causing cell lysis (Pfeifer, 1988).

- The DNA polymerase inhibitor aphidicolin prevents cell division and often causes the formation of elongated cells (Forterre et al., 1984; Schinzel and Burger, 1984).

- Certain antitumor drugs that act on topoisomerase II (adriamycin, daunorubicin, etoposide) and drugs that act on actomyosin (cytochalasin B and D) or on tubulin (vincristine, podophyllotoxin, nocodazole) inhibit *Halobacterium salinarum* (Sioud et al., 1987).

- Inhibition of halophilic Archaea by coumarin and quinolone antibacterial compounds presented evidence for the presence of DNA gyrase-like enzymes (Sioud et al., 1988). The quinolone compound ciprofloxacin inhibited most *Haloferax* and *Haloarcula* species at concentrations of 25–60 µg/ml. *Halobacterium*

cells proved less sensitive. At sublethal concentrations swelling and elongation of the cells were observed. Sensitivity to ciprofloxacin and other quinolone derivatives (norfloxacin, perfloxacin) was decreased at increased magnesium concentrations (Oren, 1996a; Sioud et al., 1988). *Haloferax volcanii* became more resistant when the magnesium concentration in the growth medium was increased. Alkaliphiles such as *Natronomonas pharaonis* are very sensitive (Oren, 1996a).

At least certain species are sensitive to gardimycin (inhibiting cell wall biosynthesis), to virginiamycin (acting on the protein synthesis machinery), to monensin and lasalocid (which target the cell membranes) (Hilpert et al., 1981), and to amphotericin B, vibriostat O/129, sulfafurazole, and josamycin (Tindall, 1992). The usefulness of these antibiotics and antibacterials for differentiation purposes in taxonomic studies has not yet been systematically evaluated.

Bile acids at low concentrations cause lysis of the cell envelopes of non-coccid halophilic Archaea and are potent growth inhibitors (Dussault 1956a; Dussault 1956b; Kamekura and Seno, 1991; Kamekura et al., 1988).

Surface layers

The non-coccoid representatives of the *Halobacteriales* possess an S-layer cell wall, whose main constituent is a high molecular weight glycoprotein. This glycoprotein cell wall is responsible for maintaining the native cell shape. Electron micrographs show a hexagonal pattern of protein subunits (Houwink, 1956), and high-resolution electron microscopy enabled a detailed three-dimensional reconstruction of the wall structure of *Haloferax volcanii* (Kessel et al., 1988a; Kessel et al., 1988b) and *Haloarcula japonica* (Nishiyama et al., 1992). In *Halobacterium salinarum* the high molecular weight glycoprotein makes up 40–50% of the wall protein, the remainder consisting of 15–20 proteins of smaller size (Mescher and Strominger, 1976a; Mescher and Strominger, 1976b; Mescher et al., 1974).

The primary structure of the structural cell wall glycoprotein of *Halobacterium salinarum* has been elucidated. Gene cloning and sequencing yielded detailed information on the structure of the S-layer and its biosynthesis (Lechner and Sumper, 1987; Lechner and Wieland, 1989; Lechner et al., 1985; Mescher, 1981; Paul and Wieland, 1987; Paul et al., 1986; Sumper, 1987; Wieland, 1988; Wieland et al., 1980; Wieland et al., 1982). The S-layer glycoprotein (molecular mass about 120 kDa) consists of a 87 kDa core protein rich in acidic amino acids, containing acidic and neutral saccharide chains attached in a manner resembling animal proteoglycans (Lechner and

Sumper, 1987; Lechner and Wieland, 1989; Kandler and König, 1993; Sumper, 1987).

- A single large (around 10 kDa) acidic glycosaminoglycan composed of 10–15 repeats of a branched sulfated (2 SO_4^{2-}) pentasaccharide, containing galacturonic acid, is bound to the sub NH_2 -terminal asparagine via a special direct asparaginyl GalNAc N-linkage (Paul and Wieland, 1987; Paul et al., 1986). This saccharide complex is considered as the main shape-maintaining component of the S-layer. When its synthesis is inhibited by bacitracin, the rod-shaped cells are converted to spheres (Lechner and Wieland, 1989; Mescher and Strominger, 1976a; Mescher and Strominger, 1976b).

- Low molecular weight tetrasaccharide units (about 10 copies per molecule), composed of 2–3 sulfated hexuronic acid residues (GlcUA, IdUA) attached to a glucose residue, are bound by a direct N-linkage to asparagine (Lechner and Wieland, 1989).

- Collagen-like O-linked glucosyl-(α -1 \rightarrow 2)-galactoside disaccharide units (about 12–15 per molecule) are bound via threonines clustered on the protein core domain 755–774 on top of the cell membrane, close to the postulated transmembranal COO^- terminal domain (Paul and Wieland, 1987; Wieland, 1988).

Figure 6 presents a model of the *Halobacterium salinarum* cell wall glycoprotein.

The primary structure of the protein backbone and the mode of glycosylation may vary among the species. The glycosylation pattern of *Haloferax volcanii* involves both N- and O-glycosidic bonds [glucosyl-(1 \rightarrow 2)-galactose disaccharides O-linked to threonine residues], in a pattern that differs from that of *Halobacterium salinarum* (Sumper et al., 1990). The S-layer protein of *Haloferax volcanii* has seven N-glycosylation sites, versus 12 in *Halobacterium salinarum* (including the sub NH_2 -terminal, negatively charged repeating unit saccharide which is absent in *Haloferax volcanii*). The N-linked oligosaccharides of *Haloferax volcanii* are (β -1 \rightarrow 4)-linked repeating glucose residues attached via asparaginyl-glucose linkages (Mengele and Sumper, 1992). It has been suggested that the difference in charge density between the extremely halophilic *Halobacterium salinarum* and *Haloferax volcanii*, a species designated as a moderate halophile with high magnesium tolerance (Mullakhanbhai and Larsen, 1975), may be related to their difference in salt requirement (Mengele and Sumper, 1992). *Halorubrum distributum* was reported to produce thick-walled cyst-like structures, probably representing resting stages (Kostrikina et al., 1991). No information is available as yet on the cell wall structure of these cysts as compared to that of cells in growing cultures.

Fig. 6. Model of the cell wall glycoprotein of *Halobacterium salinarum*, based on data presented by Lechner and Wieland, 1989. GalNAc = N-acetylgalactosamine; GalUA = galacturonic acid; Glc = glucose; GlcNAc = N-acetylglucosamine; GlcUA = glucuronic acid; IdUA = iduronic acid.

The glycoprotein cell wall requires high NaCl concentrations for stability. Similar to most other proteins of halophilic Archaea, the wall protein denaturates when suspended in distilled water. As a result, cells lyse in the absence of salt due to the denaturation and dissolution of the cell wall (Kushner, 1964; Mohr and Larsen, 1963). In addition to high NaCl concentrations, relatively high concentrations of magnesium or other divalent cations are required to maintain the structural stability of the glycoprotein cell wall. When suspended in media lacking magnesium, even in the presence of saturated NaCl concentrations, cells of many species become rounded with the formation of spheroplasts. This phenomenon was documented in studies of *Haloarcula marismortui*, *Haloferax volcanii* (Cohen et al., 1983), and *Haloarcula japonica* (Horikoshi et al., 1993; Nakamura et al., 1992). Concentrations as high as 20–50 mM magnesium may be required in these species to protect the intact morphology of the cell wall. Some magnesium may even be required for the structural stability and morphology of alkaliphilic rods. A not yet formally described rod-shaped species, isolated from a soda lake in India, becomes rounded when suspended at magnesium concentrations below 2 mM (Upasani and Desai, 1990). Spheroplast formation can often be induced by EDTA treatment, and this property has proved of much use in genetic transformation protocols (Dyall-Smith, 1999).

Halococcus species possess a thick sulfated heteropolysaccharide cell wall that does not require high salt concentrations to maintain its rigidity (Steensland and Larsen, 1971). The structure of the polysaccharide wall of *Halococcus morrhuae* has been elucidated in part (Fig. 7). Sulfate groups are linked to hydroxyl groups in

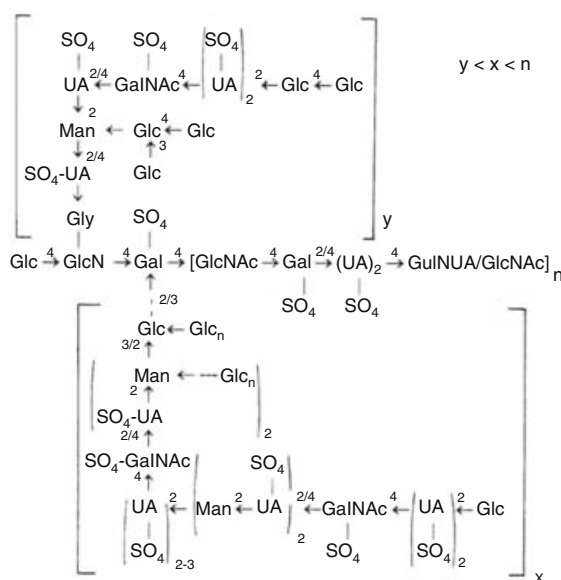

Fig. 7. The tentative structure of the cell wall polymer of *Halococcus morrhuae* (after Schleifer et al., 1982). Gal = galactose; GalNAc = N-acetylgalactosamine; Glc = glucose; GlcNAc = N-acetylglucosamine; Gly = glycine; GulNUA = N-acetylgulosaminuronic acid; Man = mannose; UA = uronic acid.

positions 2 or 3 or both of uronic acids, galactose and galactosamine residues. Glucose, galactose, galacturonic acid and all amino sugars are 1→4 glycosidically linked to the cell wall polymer. Part of the glucose, galactose, and to a lesser extent mannose residues possess more than two glycosidic linkages and represent possible branching points. Glycine residues may play a role in connecting glycan strands through pep-

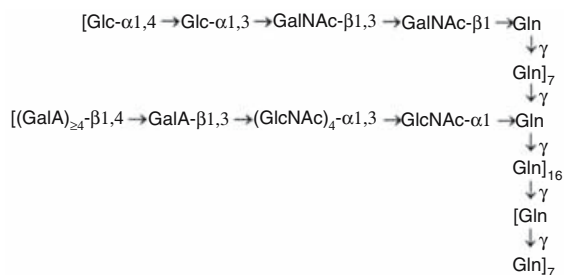

Fig. 8. The tentative structure of the cell wall polymer of *Natronococcus occultus* (after Niemetz et al., 1997). GalA = galactonic acid; GalNAc = N-acetylgalactosamine; Glc = glucose; GlcNAc = N-acetylglucosamine; Gln = glutamine.

tide linkages between the amino groups of glucosamine and the carboxyl group of an uronic acid or gulosaminuronic acid (Schleifer et al., 1982; Steber and Schleifer, 1975; Steber and Schleifer, 1979).

The coccoid *Natronococcus occultus* also has a thick cell wall that retains its shape in the absence of salt. Its structure differs greatly from that of the cell wall polymer of *Halococcus*, and it consists of repeating units of a poly(L-glutamine) glycoconjugate (Niemetz et al., 1997). Figure 8 presents a model of this structure.

Several species of halophilic Archaea, notably of the genus *Haloferax*, excrete massive amounts of exopolysaccharides (Paramonov et al., 1998; Parolis et al., 1996; Severina et al., 1989; Severina et al., 1990). The structure of the exopolysaccharide of *Haloferax mediterranei* was recently identified as consisting of repeating units of:

(Parolis et al., 1996). The polysaccharide excreted by *Haloferax gibbonsii* has a different structure:

(Paramonov et al., 1998).

In accordance with the variations in the surface layer structure, the halophilic Archaea display a considerable antigenic diversity with limited cross-reaction between the species. Antigenic fingerprinting may thus be useful not only for rapid identification but also for studying the species composition of natural communities

(Conway de Macario et al., 1986). Classic immunological techniques may be hampered by the fact that antibodies may not or only poorly react in the presence of salt concentrations approaching saturation. However, antibodies against halobacterial flagella raised in chicken were shown to interact with the antigen also at 4 M NaCl (Alam and Oesterhelt, 1984a). Also typing the surface layers with different lectins binding to specific sugar residues has been employed in the characterization of halophilic Archaea (Gilboa-Garber et al., 1998).

Polar lipids

Being Archaea, the members of the *Halobacteriales* possess lipids based on branched 20-carbon (phytanyl) and sometimes also 25-carbon (sesquiterpanyl) chains bound to glycerol by ether bonds. A great variety of neutral and polar lipids, the last including phospholipids, sulfolipids, and glycolipids, can be encountered in the different representatives of the group. The types of polar lipids present have been used as an important characteristic in the taxonomic classification of strains. Until recently the presence of certain glycolipids was used as a diagnostic trait characteristic for many of the genera recognized within the *Halobacteriaceae* (Torreblanca et al., 1986). In addition, the polar lipid composition of biomass collected from such environments as the Dead Sea or saltern crystallizer ponds has been used as a chemotaxonomic tool to obtain information on the type(s) of halophilic Archaea present in natural communities (Oren, 1994c; Oren and Gurevich, 1993; Oren et al., 1996c). During recent years, however, the increased emphasis on the use of 16S rDNA sequence comparisons in the classification of halophilic Archaea has led to the creation of a number of new genera, and many species had to be reclassified. In the present classification (see also Tables 2–6) members of one genus may contain greatly different glycolipids, and the presence of a certain glycolipid may now be shared by representatives of more than one genus. Details on the lipid composition of halophilic Archaea, the biosynthetic pathways involved in the synthesis of the lipids, and the analytical methods used in their characterization may be found in several reviews (Kamekura and Kates, 1988; Kamekura, 1993; Kamekura, 1998; Kates, 1993; Kates, 1996; Kates and Kushwaha, 1995; Kates and Moldoveanu, 1991). One- or two-dimensional thin-layer chromatographic procedures are useful for the rapid characterization of polar lipid patterns in halophilic Archaea (Norton et al., 1993; Tindall, 1990a; Tindall, 1990b; Torreblanca et al., 1986). Fast-atom-bombardment mass spectrometry has also been suggested as a rapid means of

Fig. 9. Core lipids of halophilic Archaea of the family *Halobacteriaceae*: 2,3-di-*O*-phytanyl-*sn*-glycerol (C_{20},C_{20}) (a), 2-*O*-sesterterpanyl-3-*O*-phytanyl-*sn*-glycerol (C_{25},C_{20}) (b), and 2,3-di-*O*-sesterterpanyl-*sn*-glycerol (C_{25},C_{25}) (c).

identifying polar lipids of the *Halobacteriaceae* (Fredrickson et al., 1989a; Klöppel and Fredrickson, 1991). For a detailed structure elucidation, techniques such as mass spectrometry and nuclear magnetic resonance spectroscopy are among the methods used.

The diether core lipid that forms the basis for most of the polar lipid structures present in the halophilic Archaea of the family *Halobacteriaceae* is 2,3-di-*O*-phytanyl-*sn*-glycerol, further abbreviated as C_{20},C_{20} (Fig. 9a). Certain species, however, contain in addition the asymmetric 2-*O*-sesterterpanyl-3-*O*-phytanyl-*sn*-glycerol (C_{25},C_{20}) in different amounts (Fig. 9b). The C_{25},C_{20} core lipid has been detected in many of the alkaliphilic types and in the neutrophilic *Natrialba asiatica* (Kamekura and Dyall-Smith, 1995; Matsubara et al., 1994), the genera *Natrinema* (McGenity et al., 1998) and *Halococcus*, and in “*Halobacterium halobium* IAM13167,” which may be a *Halobacterium salinarum* strain (Morita et al., 1998). Sometimes 2,3-di-*O*-sesterterpanyl-*sn*-glycerol (C_{25},C_{25}) (Fig. 9c) is encountered as a minor component as well (De Rosa et al., 1982; De Rosa et al., 1983). Thin-layer chromatographic procedures have been developed to separate the C_{20},C_{20} and C_{25},C_{20} lipid species (Ross et al., 1981). Different haloalkaliphilic Archaea contain C_{20},C_{20} and C_{25},C_{20} in different proportions, and strains can be found in which as much as 89% or as little as 0.1% of the lipids are based on the C_{25},C_{20} core lipid structure (Tindall, 1985). The ratio between C_{20},C_{20} and C_{25},C_{20} lipids may depend also on growth conditions, as shown in the alkaliphiles *Natronobacterium gregoryi* and *Natrialba magadii*, in which increasing medium salinity leads to

an increased proportion of C_{25},C_{20} (Morth and Tindall, 1985a; Morth and Tindall, 1985b; Tindall et al., 1991). In most cases the hydrophobic chains are fully saturated, but the occurrence of unsaturated phytanyl (“phytenyl”) side chains has been documented in *Halorubrum lacusprofundi* from Deep Lake, Antarctica, a strain able to grow at temperatures down to 4 °C (Franzmann et al., 1988; Fredrickson et al., 1989b). Introduction of double bonds in the carbon chains is probably important in the regulation of membrane fluidity in this cold-adapted species. In *Halobacterium salinarum*, double bonds appear transiently during the biosynthesis of the phytanyl chains (Moldoveanu and Kates, 1988; Fredrickson et al., 1989b).

Polar lipid structures are all derivatives of the C_{20},C_{20} or C_{25},C_{20} core lipids. All halophilic Archaea known thus far contain the diether derivatives of phosphatidyl glycerol (PG) and the methyl ester of phosphatidyl glycerophosphate (Me-PGP) (Fig. 10a,b). The presence of the methyl ester group in the Me-PGP structure was recognized only relatively recently (Kates, 1996; Kates et al., 1993), though it was already suggested from fast bombardment mass spectrometry data published in 1989 (Fredrickson et al., 1989b). The ratio between the amount of PG and Me-PGP present may depend on growth conditions. In *Natronococcus occultus* grown at increased salt concentrations the relative amount of PG(C_{20},C_{20}) decreases with a concomitant increase in Me-PGP(C_{25},C_{20}), while PG(C_{25},C_{20}) and Me-PGP(C_{20},C_{20}) remain unchanged (Tindall et al., 1991). PG and Me-PGP are the only phospholipids identified in most neutrophilic representatives of the *Halobacteriales*. Other unidentified phospholipids have been detected in the genus *Natrinema* (McGenity et al., 1998). In *Natronococcus occultus* a phospholipid with a cyclic phosphate group has been identified: 2,3-di-*O*-phytanyl-*sn*-glycero-1-phosphoryl-3'-*sn* glycerol-1,2-cyclic phosphate (Lanzotti et al., 1989) (Fig. 10c). Additional, yet unidentified phospholipids are present in some haloalkaliphiles (De Rosa et al., 1988; Morth and Tindall, 1985a; Tindall, 1985).

Phosphatidylglycerosulfate (PGS, Fig. 10d) is present in many neutrophilic species (Hancock and Kates, 1973). Its absence in certain genera (*Haloferax*, *Natrialba*, *Halobaculum*, *Halococcus*, *Halogeometricum*) is a useful diagnostic feature in the classification of the *Halobacteriaceae*, and its presence or absence may vary even of different species within a single genus, as the case of *Natrinema* shows (Table 6). The alkaliphilic members characterized thus far all lack PGS.

A variety of glycolipids has been identified in different members of the *Halobacteriales*. Di-

Fig. 10. Structure of the isoprenyl diether derivatives of phosphatidyl glycerol (PG) (a), the methyl ester of phosphatidyl glycerophosphate (Me-PGP) (b), the cyclic PGP of *Natronococcus occultus* (c) and phosphatidyl glycerosulfate (PGS) (d).

tri-, and tetraglycosyl diether lipids occur, some of them carrying sulfate groups on the sugar moieties. Most haloalkaliphilic members lack substantial amounts of glycolipids, but there are exceptions: the alkaliphilic strain SSL1, isolated from a soda lake in India, possesses DGD-4 (Upasani et al., 1994). Figure 11 presents some of the glycolipids that have been identified in different representatives of the group (unless indicated otherwise, all sugar residues are in the pyranose conformation):

- DGD-1, 1-*O*-[β-D-mannose-(1'→2')-α-D-glucose]-2,3-di-*O*-phytanyl-*sn*-glycerol (Fig. 11a), is found in minor amounts in *Haloferax* species.

- DGD-2, a minor diglyceride lipid of unknown structure, containing mannose and glucose, is found as a minor component in *Haloarcula* species.

- DGD-4, documented from the haloalkaliphilic strain SSL1, isolated from an Indian soda lake (Upasani et al., 1994). Two possible structures have been proposed for this glycolipid: 1-*O*-[β-1'→6'-glucose-(1'→1')-α-D-glucose]-2,3-di-*O*-phytanyl-*sn*-glycerol and 1-*O*-[α-1'→6'-

glucose-(1'→1')-β-D-glucose]-2,3-di-*O*-phytanyl-*sn*-glycerol (Fig. 11b,c). It remains to be ascertained which of these is the correct structure.

- S-DGD-1, 1-*O*-[α-D-mannose-(6'-SO₃H)-(1'→2')-α-D-glucose]-2,3-di-*O*-phytanyl-*sn*-glycerol (Fig. 11d), being the major glycolipid in the genus *Haloferax* (Kushwaha et al., 1982a; Kushwaha et al., 1982b). It is found also as sole or minor glycolipid in the genera *Halobaculum* (Oren et al., 1996c) and *Halococcus* and was reported also from *Halorubrum saccharovororum* (Lanzotti et al., 1988). S-DGD-1 was found also as the major or sole glycolipid in the archaeal biomass of the Dead Sea (Oren and Gurevich, 1993) and saltern crystallizer ponds in Eilat, Israel (Oren, 1994c). Lipid analysis of field samples also suggested that S-DGD-1 may be the main glycolipid of the gas vesicles containing square Archaea (Oren et al., 1996c).

- S-DGD-3, 1-*O*-[α-D-mannose-(2'-SO₃H)-α-D-(1'→4')-glucose]-2,3-di-*O*-phytanyl-*sn*-glycerol (Fig. 11e), is the glycolipid of several *Halorubrum* species, including *Halorubrum sodomense* (Trincone et al., 1990) and *Halorubrum lacusprofundi* (Tindall, 1990a).

Fig. 11. Structure of some glycolipids found in members of the *Halobacteriales*: DGD-1 (a), proposed structures for DGD-4 (b,c), S-DGD-1 (d), S-DGD-3 (e), S-DGD-5 (f), S₂-DGD-1 (g), TGD-1 (h), TGD-2 (i), S-TGD-1 (j), TeGD (k), and S-TeGD (l).

• S-DGD-5 ([1-*O*-mannose-(2'-SO₃H)-α-D-(1'→2')-glucose]-2,3-di-*O*-phytanyl-*sn*-glycerol) (Fig. 11f) is found in *Halorubrum trapanicum* (Trincone et al., 1993).

• S₂-DGD-1, a bis-sulfated glycolipid, 1-*O*-[α-D-mannose-(2',6'-SO₃H)-α-D-(1'→2')-glucose]-2,3-di-*O*-phytanyl- or phytanyl sesterterpenyl-*sn*-glycerol (Fig. 11g), is found in *Natrialba asiatica* (Kates, 1996; Matsubara et al., 1994; Onishi et al., 1985).

• T GD-1, 1-*O*-[β-D-galactose-(1'→6')-α-D-mannose-(1'→2')-α-D-glucose]-2,3-di-*O*-phytanyl-*sn*-glycerol (Fig. 11h), is a minor glycolipid of *Halobacterium salinarum* (Smallbone and Kates, 1981).

• T GD-2, 1-*O*-[β-D-glucose-(1'→6')-α-D-mannose-(1'→2')-α-D-glucose]-2,3-di-*O*-phytanyl-*sn*-glycerol (Fig. 11i), is the sole or major glycolipid of most *Haloarcula* species (Evans et al., 1980).

Fig. 11. *Continued*

- S-TGD-1, 1-*O*-[β-D-galactose-(3'-SO₃H)-(1'→6')-α-D-mannose-(1'→2')-α-D-glucose]-2,3-di-*O*-phytanyl-*sn*-glycerol (Fig. 11j), is found in the genus *Halobacterium* (Kates, 1978; Kates and Deroo, 1973).

- TeGD, 1-*O*-[β-D-galactose-(1'→6')-α-D-mannose-(3'←1')-α-D-galactofuranose)-(1'→2')-α-D-glucose]-2,3-di-*O*-phytanyl-*sn*-glycerol (Fig. 11k), is a minor glycolipid of *Halobacterium salinarum* (Smallbone and Kates, 1981).

- S-TeGD, 1-*O*-[β-D-galactose-(3'-SO₃H)-(1'→6')-α-D-mannose-(3'←1')-α-D-galactofuranose)-(1'→2')-α-D-glucose]-2,3-di-*O*-phytanyl-*sn*-glycerol (Fig. 11l), is found in *Halobacterium* (Smallbone and Kates, 1981).

While considerable knowledge has accumulated on the nature of the glycolipids present in different members of the *Halobacteriales*, some controversies remain. Confusion still exists on the correct structures of the glycolipids that occur in different members of the genus *Halorubrum*. Kamekura, 1998 stated that S-DGD-3 is the main glycolipid in the genus *Halorubrum*. However, Lanzotti et al., 1988 reported that the *Halorubrum saccharovorum* glycolipid is identical to S-DGD-1 from *Haloferrax*. To add to the confusion, different isolates designated as *Halorubrum saccharovorum* were found to contain different glycolipids (Tindall, 1990b).

Additional glycolipids occur within the halophilic Archaea. An as yet unidentified halophile was isolated from a saltern in Guerrero Negro, Baja California, Mexico. It is able to grow anaerobically in the presence of nitrate and possesses two novel unidentified phosphoglycolipids in addition to PG, Me-PGP, a diglycosyl diether and a sulfated diglycosyl diether (Tindall et al., 1987).

Glycolipids have become valuable taxonomic markers in the classification of halophilic Archaea, as the type(s) of glycolipids present are constant for any species. A single exception has been reported thus far: a *Halococcus* strain (incorrectly designated *Sarcina marina*) was found to contain an unidentified triglycosyl diglyceride when grown at 34°C, but a diglycosyl diglyceride became the major component when the cells were grown at 20°C (Hunter et al., 1981). The ratios in which the different polar lipids occur in the membrane may vary according to the growth conditions: when grown at very high salt concentrations *Haloferrax mediterranei* showed an increase in S-DGD-1 with a decrease in PG (Kamekura and Kates, 1988; Kushwaha et al., 1982b). *Natronococcus occultus* showed an increase in Me-PGP(C₂₅,C₂₀) and a decrease in PG(C₂₀,C₂₀) with increasing medium salinity. In addition, an increase was found in the amount of glycine betaine associated with the cell mem-

Fig. 12. Some neutral lipids found in the *Halobacteriales*: squalene (a), dihydrosqualene (b), tetrahydrosqualene (c), and dehydrosqualene (d).

brane. The content of Me-PGP(C_{20} , C_{20}) and PG(C_{25} , C_{20}) was independent of the salt concentration at which the cells were grown (Nicolaus et al., 1989).

Neutral lipids

Neutral lipids may represent about 10% of the total lipid content of halophilic Archaea of the order *Halobacteriales* (Kamekura and Kates, 1988). The following types have been reported:

- C_{20} isoprenoid lipids: geranylgeraniol.
- Neutral phytanyl ethers of glycerol: DL-*O*-phytanyl-*sn*-glycerol and 2,3-di-*O*-phytanyl-*sn*-glycerol (Kushwaha and Kates, 1978).
- C_{30} -isoprenoid compounds: squalene, dihydrosqualene, tetrahydrosqualene, and dehydrosqualene (Kushwaha et al., 1972; Kushwaha et al., 1974) (Fig. 12). Squalenes may make up about 36% of the total neutral lipids of *Halobacterium salinarum* (Kushwaha et al., 1972; Kushwaha et al., 1974). Occurrence of squalene derivatives has been reported also in *Haloferax volcanii* (Mullakhanbhai and Francis, 1972).
- Indole has been indicated as a neutral lipid in *Halobacterium salinarum* and *Halococcus* sp. (Kushwaha et al., 1977).

• Carotenoids and quinones also make up part of the neutral lipids, and these are discussed separately.

Information on the biosynthetic pathways of different lipids mentioned above has been presented by Kamekura and Kates, 1988 and Kushwaha and Kates, 1979.

In addition to the isoprenoid hydrophobic chains characteristic of the archaeal domain, straight-chain fatty acids can be found in members of the *Halobacteriales* in limited amounts. The presence of a fatty acid synthetase has been demonstrated in *Halobacterium salinarum*. Activities measured were low, and the enzyme

was inhibited by salt at the concentrations reported to occur intracellularly (Pugh et al., 1971). The straight-chain fatty acids produced are not incorporated into the membrane lipids but serve to acylate membrane proteins to make them more hydrophobic (Pugh and Kates, 1994).

Carotenoid pigments

Most representatives of the *Halobacteriales* are brightly red-orange, colored by a high content of carotenoid pigments in their cell membrane. *Natrialba asiatica*, a species lacking substantial amounts of carotenoids, is a rare exception to the rule (Kamekura and Dyll-Smith, 1995). However, white mutants of species such as *Halobacterium salinarum* can easily be isolated. In the dark, such mutants grow as well as the red wild type, but when incubated at high light intensities approaching those of full sunlight, the white mutants are outcompeted by the pigmented parent strain, demonstrating the role of the carotenoid pigments in protecting the cells against light damage (Dundas and Larsen, 1962). Carotenoid pigments in *Halobacterium salinarum* were also claimed to protect against UV radiation and aid in photoreactivation (Wu et al., 1983), but the data presented are not fully convincing, as little difference in survival can be seen in the red wild-type strain and the colorless mutant.

Most carotenoids of the halophilic Archaea are C_{50} straight-chain derivatives of α -bacterioruberin. The most abundant carotenoid species encountered are α -bacterioruberin, monoanhydrobacterioruberin, and bisanhydrobacterioruberin (Kelly et al., 1970; Kushwaha et al., 1974; Kushwaha et al., 1975; Fig. 13a,b,c). Several other derivatives have been found in minor amounts, such as the dodecaene C_{50} carotenoids 3',4'-dihydromonoanhydrobacterioruberin (Fig. 13d), haloxanthin (a 3',4'-dihydromonoanhydrobacterioruberin derivative with a novel peroxide end group) (Fig. 13e), and 3',4'-epoxymonoanhydrobacterioruberin of *Haloferax volcanii* (Rønekleiv et al., 1995) (Fig. 13f).

C_{40} carotenoids are generally found in small amounts, lycopene and β -carotene being the most abundant (Kushwaha et al., 1982a; Tindall, 1992). Among the other types identified are lycopersene, *cis*- and *trans*-phytoene, *cis*- and *trans*-phytofluene, neo- α -carotene, and neo- β -carotene. The low concentrations of these compounds suggest that they may serve as precursors for the synthesis of retinal, lycopene, and the C_{50} red carotenoid pigments of the bacterioruberin group. A recent report on the occurrence of major amounts of the C_{40} carotenoids 3-hydroxyechinenone and *trans*-astaxanthin in

Fig. 13. Structure of carotenoid pigments found in members of the *Halobacteriales*: α -bacterioruberin (a), monoanhydrobacterioruberin (b), bis-anhydrobacterioruberin (c), 3',4'-dihydromonoanhydrobacterioruberin (d), haloxanthin (e), and 3',4'-epoxymonoanhydrobacterioruberin (f).

Halobacterium salinarum, *Haloarcula hispanica*, and *Haloferax mediterranei* (Calo et al., 1995) remains to be confirmed. It was stated that in *Halobacterium salinarum* 24% by weight of pigment is 3-hydroxyechinenone and 11% is *trans*-astaxanthin. However, identification was based on HPLC analysis only.

The pigment content of the cells may depend on their nutritional status (Gochnauer et al., 1972; Kushwaha and Kates, 1979), and also the salinity may play a role: certain *Haloferax* species are pigmented when grown at low salinity (e.g., 15%), while at higher salt concentrations (e.g., 25%) they may be almost colorless (Kushwaha et al., 1982a; Rodriguez-Valera et al., 1980a). *Haloferax mediterranei*, a species that at high salinity is only weakly pigmented, produced massive amounts of bacterioruberin pigments when incubated at 5% salt, a concentration too low to support growth (D'Souza et al., 1997).

Respiratory quinones

The major respiratory quinones in the *Halobacteriales* are two menaquinones with 8 isoprenoid units: MK-8 (Fig. 15a) and MK-8(H_2) (Fig. 15b) (Collins et al., 1981; Tindall and Collins, 1986a). Quinones are present in large amounts and may amount to about 9% of the total neutral lipid content of the cells (Kamekura and Kates,

Fig. 14. C_{40} carotenoids phytoene (a) and lycopene (b), and the all-*trans* form (c) and the 13-*cis* form (d) of retinal, found in bacteriorhodopsin, halorhodopsin, and the sensory rhodopsins.

1988a). A close examination of the quinones of *Halococcus morrhuae* showed that the saturation in MK-8(H_2) involves the terminal double bond [MK-8(VIII- H_2)] (Tindall and Collins, 1986). The relative amounts of MK-8 and MK-8(VIII- H_2) may depend on the growth conditions (Tindall,

Fig. 15. Structure of respiratory quinones found in members of the *Halobacteriales*: 2-methyl-3-octaprenyl-1,4-naphthoquinone (menaquinone-8, MK-8) (a); 2-methyl-3-VIII-dihydro-octaprenyl-1,4-naphthoquinone (dihydromenaquinone 8, MK-8[VIII-H₂]) (b).

1992; Tindall et al., 1991). Novel types of methylated menaquinones were detected in *Natronobacterium gregoryi*, which contains a range of octaprenyl menaquinones, monomethylated, and dimethylated menaquinones (Collins and Tindall, 1987).

RETINAL PIGMENTS Four retinal-containing proteins have been identified in representatives of the *Halobacteriales*: bacteriorhodopsin—an outward light-driven proton pump, halorhodopsin—an inward light-driven chloride pump, and two sensory rhodopsins, involved in light-sensing for phototaxis. The presence of the unique retinal proteins has greatly stimulated the interest of the scientific community in the halophilic Archaea, and during the almost three decades that have passed since the structure and function of bacteriorhodopsin were discovered, more publications have been written on the retinal pigments than on all other aspects of the biology of the *Halobacteriales* combined. For more in-depth information on the biology, biochemistry, and biophysics of the retinal proteins specialized reviews should be consulted (e.g., Bickel-Sandkötter et al., 1996; Lanyi, 1993a; Lanyi and Váró 1995; Oesterhelt, 1995; Skulachev, 1993; Stoeckenius and Bogomolni, 1982; and Wagner and Linhardt, 1988).

The purple pigment bacteriorhodopsin was first identified in *Halobacterium salinarum* (Oesterhelt and Stoeckenius, 1971). This 27-kDa protein, carrying retinal as a prosthetic group (Fig. 14c–d), is located in the cell membrane in certain species, localized in patches called purple membrane. The protein serves as an outward proton pump. Upon excitation by light of the proper wavelength (absorption maximum 570 nm), protons are extruded from the cyto-

plasm to the outside of the cell (for reviews see Lanyi, 1993a; Lanyi, 1993b; Lanyi, 1997). The pathway of the proton transfer through the molecule has now been elucidated at high resolution (Luecke et al., 1998). The proton gradient thus formed is used to drive energy-requiring processes in the cell, including the phosphorylation of ADP to ATP (Danon and Stoeckenius, 1974). Under the proper conditions, *Halobacterium salinarum* produces the pigment in large quantities, imparting a purple color to the cultures. Formation of bacteriorhodopsin does not seem to be widespread among the *Halobacteriales*. Another species able to synthesize large amounts of bacteriorhodopsin, probably also located in its purple membrane, is *Halorubrum sodomense* (Oren, 1983a). The high content of bacteriorhodopsin detected in the bacterial community in the Dead Sea in 1980–82 (Oren, 1983b; Oren and Shilo, 1981) may be attributed to that species. Smaller amounts of retinal protein proton pumps, sometimes designated archaeorhodopsins and cruxrhodopsins, were found in yet unidentified isolates from Australia (Mukohata et al., 1988; Mukohata et al., 1991) and different *Haloarcula* species (*Haloarcula vallismortis*, *Haloarcula argentinensis*) (Kitajima et al., 1996; Mukohata, 1994; Sugiyama et al., 1994; Tateno et al., 1994). In addition, retinal pigments were found in unidentified strains obtained from the Gavish Sabkha (Sinai, Egypt) (Stoeckenius et al., 1985). The gene encoding for bacteriorhodopsin was found even in an isolate that never expresses it (Kamekura et al., 1998). Studies of the bacteriorhodopsin gene cluster of *Halobacterium salinarum* have shown that expression of the protein is induced by low oxygen tension and by light (Betlach et al., 1986; Shand and Betlach, 1991). Presence of bacteriorhodopsin, which enables cells to use light energy directly, is of obvious ecological advantage. It was shown that light can relieve energy starvation at low nutrient concentrations in cells containing the pigment (Brock and Petersen, 1976), and in chemostat cultures, light enhanced growth rate and growth yields (Rodriguez-Valera et al., 1983b; Rogers and Morris, 1978). *Halobacterium salinarum* cells containing bacteriorhodopsin also are able to grow anaerobically in the light.

The second retinal protein, also first discovered in *Halobacterium salinarum*, is halorhodopsin. The structure of this protein is quite similar to that of bacteriorhodopsin, but it acts as a chloride pump: excitation by light (absorption maximum 580 nm) causes the inward transport of chloride ions from the medium (Schobert and Lanyi, 1982). Inward chloride transport is important in maintaining the proper ionic balance and is essential for cell growth. Other properties of the pigment can be found in a number of reviews

(Lanyi, 1986; Lanyi et al., 1990; Oesterhelt, 1995). No systematic survey has been performed as yet of the presence of halorhodopsin among the different genera and species within the *Halobacteriales*, but it is probably more widely distributed than bacteriorhodopsin. Halorhodopsin was in several haloalkaliphilic Archaea (Bivin and Stoeckenius, 1986), and the halorhodopsin of *Natronomonas pharaonis* has been studied in detail (Lanyi et al., 1990).

Halobacterium salinarum contains two sensory rhodopsins involved in light sensing for phototaxis. Sensory rhodopsin I is a green light receptor (light to which the cells are attracted), and sensory rhodopsin II, also termed phoborhodopsin, is a blue light receptor (light that acts as a repellent). In-depth characterizations of the sensory rhodopsin II of *Halobacterium salinarum* (Seidel et al., 1995; Zhang et al., 1996) and of *Natronomonas pharaonis* (Hirayama et al., 1992; Tomioka and Sasabe, 1995) have been published. The subject of sensory rhodopsins in halophilic Archaea has been reviewed by Bogomolni and Spudich, 1982 and by Bickel-Sandkötter et al., 1996.

PTERINS, SULFHYDRYL COMPOUNDS AND POLYAMINES Two unusual pterins have been reported to occur in *Haloarcula marismortui*: sulfohalopterins-2 (Fig. 16) and phosphohalopterins-1 (Lin and White, 1987; Lin and White, 1988). No information is available as yet on their function in the cell.

Glutathione was found to be absent in cells of halophilic Archaea, tested species including *Haloarcula marismortui*, *Haloferax volcanii*, *Halorubrum saccharovororum*, and "*Haloarcula californiae*." γ -Glutamylcysteine is present instead (Newton and Javor, 1985).

Polyamines, which are useful chemotaxonomic markers in many groups of prokaryotes, are of little or no taxonomic value in the halophilic

Archaea. Concentrations of polyamines encountered are always very low. Agmatine, putrescine, spermidine, and spermine have been detected in different representatives (CartenfFarina et al., 1985; Hamana et al., 1985; Hamana et al., 1995; Kamekura et al., 1986; Kneifel et al., 1986). The polyamines may be derived to a large extent from the growth medium, and the cellular polyamine composition is influenced by the type of medium employed.

FLAGELLA Many members of the *Halobacteriales* are motile. They were shown to possess right-handed helical flagella (Alam and Oesterhelt, 1984; Alam et al., 1984; Houwink, 1956; Fig. 3a). Clockwise rotation results in forward movement of the cells, counterclockwise rotation in backward movement (Alam and Oesterhelt, 1984; Marwan et al., 1987; Marwan et al., 1991). The flagellin of which the flagella are built is a sulfated glycoprotein (Wieland et al., 1985).

GAS VESICLES Gas vesicles are found in a number of species: *Halobacterium salinarum* (Fig. 2a, Fig. 3b), *Haloferax mediterranei*, *Natrialba vacuolata*, *Halogeometricum borinquense* (Fig. 2g), and the flat square, not yet cultivated cells discovered by Walsby, 1980 (Fig. 2f, 4f). Expression of the potential of gas vesicle formation may be salt dependent: *Haloferax mediterranei* produces gas vesicles only at salt concentrations exceeding 17% (Englert et al., 1990; Röder and Pfeifer, 1996). The property is also easily lost by mutation. The structural and genetic aspects of the gas vesicles and the mechanisms involved in the regulation of their formation have been described in depth (DasSarma and Arora, 1997; Offner et al., 1998; Pfeifer and Englert, 1992; Pfeifer et al., 1997). The presence of gas vesicles and the ability to float to the water surface are advantageous for an aerobic bacterium living in salt saturated brines in which the solubility of oxygen is low. The advantage of possessing gas vesicles became clear during competition experiments between a *Halobacterium salinarum* mutant with a low amount of deficient gas vesicles and the wild type. In shaken culture both strains grew equally well. However, in static cultures cells of the wild type floated and dominated, probably because they competed successfully for oxygen, which was in short supply. In shallow static cultures, the mutant won the competition, an effect that was explained by its smaller protein burden, i.e., the wild type wasted much energy to produce gas vesicles, unnecessary under the conditions employed (Beard et al., 1997). The idea that gas vesicles also may be effective as a shield against harmful UV radiation was not confirmed in laboratory experiments (Simon, 1980).

Fig. 16. Structure of sulfohalopterins-2, an unusual pterin compound found in *Haloarcula marismortui*.

7S RNA A stable 7S RNA has been detected in several members of the *Halobacteriales*. In *Halobacterium salinarum* this molecule is 304 nucleotides long; in other species it may be somewhat larger (Moritz and Goebel, 1985; Moritz et al., 1985). The molecule does not make part of the ribosome, and its function in the cell is still unknown.

Habitat

Halophilic Archaea of the order *Halobacteriales* can be found in a wide variety of hypersaline ecosystems. Aquatic environments include natural salt lakes, such as the Great Salt Lake, Utah, and the Dead Sea, and saltern crystallizer ponds (Borowitzka, 1981; Javor, 1983; Javor, 1989; Oren, 1983c; Oren et al., 1988; Oren 1994a; Post, 1977; Post, 1981). The major factors determining their distribution in nature are the total salt concentration present, the ionic composition of the salts, and the availability of nutrients. Most species will not grow at total salt concentrations below 2.5–3 M; when suspended in solutions containing less than 1–2 M salt, cells will be irreversibly damaged and many species will lyse. Therefore, the presence of a sufficiently high salt concentration and absence of major salinity fluctuations are prerequisites for the development of halophilic Archaea of the order *Halobacteriales*.

In addition to the concentration of Na^+ (required in molar concentrations by all known representatives of the *Halobacteriales*), the concentration of divalent cations, especially magnesium and calcium, in the environment is of considerable ecological importance. Besides thalassohaline environments that originated by evaporation of sea water and thus reflect its ionic composition dominated by Na^+ and Cl^- , there are also athalassohaline water bodies with greatly different ionic compositions. Thus, the Dead Sea is dominated by divalent cations (presently around 1.9 M Mg^{2+} and 0.4 M Ca^{2+} , in addition to about 1.7 M Na^+ and 0.14 M K^+).

Red halophilic Archaea are also abundant in hypersaline soda lakes such as Lake Magadi (Kenya) (Tindall et al., 1980; Tindall et al., 1984), the Wadi Natrun lakes (Egypt) (Soliman and Trüper, 1982), and soda lakes in China (Wang and Tang, 1989) and India (Upasani and Desai, 1990). Alkaliphilic representatives of the *Halobacteriales* may impart a red color to such lakes. These environments are characterized by a salinity at or close to halite saturation and by high concentrations of carbonates, resulting in pH values around 10–11, often leading to the precipitation of trona ($\text{NaHCO}_3 \cdot \text{Na}_2\text{CO}_3 \cdot 2\text{H}_2\text{O}$) (Grant and Tindall, 1986).

Acidophilic types of halophilic Archaea have not yet been reported. The Dead Sea with a pH of around 6.0 is probably the most acidic environment in which mass development of halophilic Archaea has been observed (Oren, 1983c; Oren et al., 1988; Oren and Gurevich, 1993). A pH of 6 approximately coincides with the lower boundary of the range of pH values that support growth of members of the *Halobacteriales*. As more acidic hypersaline environments seem to be rare or altogether nonexistent, the halophilic Archaea appear to be well adapted to the whole pH range occurring in hypersaline brines in nature.

Most halophilic Archaea have rather high temperature optima, in the range between 35 and 50°C and sometimes even higher (Shand and Perez, 1999). The ability to grow at high temperatures may be an adaptation to the often relatively high temperatures of salt lakes in tropical areas where the high rates of evaporation easily lead to the formation of hypersaline environments. However, cold-adapted strains also occur. Deep Lake, Antarctica is a hypersaline lake in which the water temperature varies according to the season between below 0 and +11.5°C. *Halorubrum lacusprofundi*, a halophilic Archaeon isolated from this lake, grows optimally at 31–37°C, but slow growth does occur down to temperatures as low as 4°C (Franzmann et al., 1988).

Halophilic Archaea also have been isolated from saline soils. Though soil environments are generally more prone to salinity fluctuations following rainfall events than hypersaline brines in salt lakes are, members of the *Halobacteriales* were found in saline soils of arid areas such as at the Mediterranean coast of Spain (Quesada et al., 1982) and in soils of plains and high mountains of the former USSR (Kulichevskaya et al., 1992; Zvyagintseva and Tarasov, 1988). These soils yielded cultures of species such as *Halorubrum distributum*, *Haloferax mediterranei*, *Haloferax volcanii*, and *Haloterrigena turkmenica*.

Members of the *Halobacteriaceae* also develop on salted food, hides, and other products to which high salt concentrations are added for preservation (Browne, 1922; Clayton and Gibbs, 1927; Harrison and Kennedy, 1922; Lochhead, 1934; Rodriguez-Valera, 1992; Shewan, 1971). Salted fish may develop a red patina, called “the pink,” caused by development of *Halobacterium* and *Halococcus* colonies. The economic damage caused by the halophilic Archaea has triggered much of the early research on these organisms. The problem may be caused to a large extent by the use of crude solar salt. During crystallization of halite from NaCl -saturated brines, cells are often trapped within liquid inclusions inside the growing crystals, and these may remain viable for months and even years (Dussault, 1958; Norton

and Grant, 1988). Different methods have been suggested to kill halophilic Archaea in contaminated solar salt, including the use of dilute acid (Kushner et al., 1965), peracetic acid vapor or ethylene oxide (Tasch and Todd, 1973; Tasch and Todd, 1974), and bile acids (Rodriguez-Valera, 1992).

To what extent the longevity of cells within salt crystals extends to hundreds of millions of years is still a point of controversy. Viable halobacteria have been recovered from salt collected from British salt mines from the Triassic (195–225 million years B.P.) and Permian (225–270 million years B.P.) periods (Norton et al., 1993). Vreeland and coworkers (Vreeland and Rosenzweig, 1999; Vreeland et al., 1998b) recently recovered a variety of halophilic Archaea from a salt mine of the Salado formation (Permian) near Carlsbad, New Mexico, including some novel types. Some of these strains may be able to degrade cellulose, a property not earlier documented within the *Halobacteriales*. However, it is difficult to assess with certainty whether these bacteria were indeed trapped within the crystals at the time of the formation of the salt deposits or whether they are of more recent origin and may have entered the salt during disturbances of the salt layer, either natural or caused by human activity. Another case in which red halophilic Archaea have been recovered from ancient geological strata is the isolation of *Halorubrum distributum* from an Upper-Devonian oilfield (Zvyagintseva et al., 1998). It is not clear whether the cells found within the salt crystals and in the deep oil deposits remained viable in a state of “suspended animation” or whether they were slowly metabolizing and possibly even growing *in situ*. Critical discussions of the intriguing findings of viable halophilic Archaea within ancient salt deposits were given by Vreeland and Powers, 1999 and by Grant et al., 1998b.

Isolation

A variety of media has been recommended for the growth of different members of the *Halobacteriales*. Table 7 gives a representative selection. Additional information on cultivation can be found in the original species descriptions (see the references given in Tables 2–6) and in reviews (DasSarma et al., 1995b; Eimhjellen, 1965; Gibbons, 1969; Larsen, 1981; Rodriguez-Valera, 1995; Tindall, 1992; Weber et al., 1982). Also the homepage of the Deutsche Sammlung von Mikroorganismen und Zellkulturen mbH (<http://www.dmsz.de>) gives access to a wealth of information. Another useful website providing descriptions of growth media and laboratory

procedures for use with the halophilic Archaea was prepared by Dyall-Smith, 1999.

Growth media often resemble the ionic composition of the environment from which the organism was isolated originally. Media used differ greatly in total salt concentration, ionic composition (e.g., high magnesium concentrations of up to 0.8 M for species isolated from the Dead Sea), and pH (9.5 and higher for the alkaliphilic species, using media very low in divalent cation concentrations). Members of the *Halobacteriales* are grown generally in complex media containing high concentrations of yeast extract, casamino acids, and similar sources of nutrients (see also Table 7). Typical doubling times in such media are from 3–4 h for *Haloferax volcanii* to 8–12 h for *Halobacterium salinarum*. The use of media with high concentrations of peptides and amino acids reflects environments such as salted fish and hides from which many isolates were obtained. It may be argued that the earlier assumption that the members of the group have a very limited metabolic potential was to a large extent because of the restricted range of compounds tested as potential substrates.

Several brands of peptone, notably Bacto-peptone (Difco), are unsuitable for the cultivation of members of the *Halobacteriales* as they cause lysis of the cells. The toxic factor present in Bacto-peptone was identified as bile acids (Kamekura et al., 1988), known since 1956 to cause lysis (when present at very low concentrations) of halophilic Archaea (Dussault, 1956a; Dussault, 1956b). Addition of starch to the medium may bind and neutralize toxic components such as bile acids (Oren, 1990a). Sugars may stimulate growth of many species. When adding sugars, proper buffering may be required to avoid acidification of the medium to values inhibitory for growth. Though light can be used as an energy source in species containing bacteriorhodopsin, no absolute requirement for light has been demonstrated for any strain, and all known members of the *Halobacteriales* grow well in the dark.

Recovery of colonies of halophilic Archaea from samples collected from nature may be enhanced by the addition of natural brine from the sampling site and a whole cell extract of *Halobacterium salinarum* as a source of stimulatory growth factors (Wais, 1988). For the selective isolation of Archaea from natural sources, inclusion of antibiotics such as penicillin or ampicillin has been recommended.

Few procedures have been described for the selective isolation of specific genera and species belonging to the *Halobacteriales*. *Halobacterium* can be selectively enriched under anaerobic conditions in medium containing L-arginine (Oren and Litchfield, 1999). *Halococcus* species may be

Table 7. A selection of media used for the cultivation of neutrophilic and alkaliphilic members of the order *Halobacteriales*.

Ingredient (g/liter) ^a	Medium no.

^a—For solid media, 20g agar/liter should be added.

^b—Sterilized separately.

Media no. 1 and 2 are suitable for the growth of *Halobacterium* and other neutrophilic extremely halophilic representatives of the group. Medium no. 3 may be used for species that require less salt, such as many *Halorubrum* species. Types that require high concentrations of magnesium, such as Dead Sea isolates, can be grown in medium no. 4 (*Haloflexax volcanii*) or 5 (*Halorubrum sodomense*, *Halobaculum gomorrense*). Media no. 6 and 7 were designed for the growth of alkaliphilic species. Additional recipes for media, including defined media, were given by Dvall-Smith (1999), Eimhjellen (1965), Gibbons (1969), Tindall (1992), and Larsen (1981).

selectively isolated by suspension of the sample in medium with a salt concentration sufficiently low to kill all other known neutrophilic halophilic Archaea, followed by cultivation in a suitable high-salinity medium. Viable *Halococcus* cells could be recovered even from sea water: 2–35 *Halococcus* colonies were obtained from 5-liter portions of Mediterranean sea water sampled 5 km off the coast of Spain (Rodriguez-Valera et al., 1979).

Chemically defined media have been designed for a number of species. Members of the genera *Haloferax* and *Haloarcula* grow on inorganic media amended with a suitable single carbon and energy source (Javor, 1984; Rodriguez-Valera et al., 1980a). In certain cases small amounts of vitamins or other growth factors may still be needed. A synthetic medium supporting good growth of *Haloferax volcanii* contains glycerol, succinate, NH_4Cl , thiamine and biotin. Also urea, histidine and glutamate can serve as single nitrogen sources in this species (Kauri et al., 1990). Defined media for more fastidious types such as different *Halobacterium salinarum* strains may contain 10–15 amino acids, nucleotides (adenylic acid, uridylic acid, and/or cytidylic acid) and other compounds (Dundas et al., 1963; Grey and Fitt, 1976; Onishi et al., 1965; Weber et al., 1982).

For solid media, higher than usual agar concentrations should be used, as the high salt concentration of the medium interferes with the solidification of the agar. A concentration of 20 g agar/liter generally gives satisfactory results. For the preparation of agar media for the haloalkaliphiles the agar should be sterilized separately from the sodium carbonate and the other alkaline components of the media. When streaking halophilic Archaea on agar plates, account should be taken that some species may be mechanically fragile, and cells are easily damaged during handling. Drying out of agar plates with the formation of salt crystals on the surface of the agar may present a serious problem in view of the often long incubation times required (up to several weeks) for colonies to appear. Incubation and storage of Petri dishes in plastic bags are then recommended.

Identification

Isolates may be identified according to the properties listed in Tables 2–6. Properties important in the identification of members of the *Halobacteriales* are based on the published list of minimal standards for the description of new taxa within the order (Oren et al., 1997a). The list of properties to be included in such descriptions includes colonial size and shape, cell morphol-

ogy, motility, pigmentation, Gram stain reaction, salt concentration required to prevent cell lysis, optimum NaCl and MgCl_2 concentrations for growth, the range of salt concentrations enabling growth, temperature and pH ranges for growth, ability of anaerobic growth in the presence of nitrate, reduction of nitrate to nitrite, formation of gas from nitrate, anaerobic growth in the presence of L-arginine, production of acids from a range of carbohydrates, ability to grow on a range of single carbon sources, catalase and oxidase activities, formation of indole, starch hydrolysis, gelatin hydrolysis, casein hydrolysis, Tween 80 hydrolysis, sensitivity to different antimicrobial compounds, characterization of polar lipids, including the types of glycolipids present and the presence or absence of PGS, G+C content of DNA, and 16S rRNA nucleotide sequence information. For the description of new species within existing genera, also DNA-DNA hybridization experiments with related species are to be performed. Further traits recommended to be included in descriptions of new taxa are electron microscopy, anaerobic growth in the presence of dimethylsulfoxide or trimethylamine *N*-oxide, phosphatase activity, urease activity, β -galactosidase activity, lysine decarboxylase activity, ornithine decarboxylase activity, presence of glycoprotein in the cell envelope, presence of poly- β -hydroxyalkanoate, presence of plasmids, and the electrophoretic pattern of cellular proteins. Procedures and approaches used for the performance of the different tests are described in the minimal standards document (Oren et al., 1997a). The Gram stain is best carried out after fixation of the cells with acetic acid (Dussault, 1955). However, the value of the Gram stain in differentiation of members of the order and family is limited. The catalase and oxidase reactions of all known species are positive.

DNA-DNA hybridization tests are still considered essential to determine whether a new isolate assigned to an existing genus represents a new species or may belong to one of the recognized species within that genus (DNA-DNA hybridization values higher than 70%) (Oren et al., 1997a). DNA-16S rRNA hybridization has been used also in taxonomic studies dealing with the group (Ross and Grant, 1985).

Preservation

Cultures may be kept on agar slopes at 4°C, to be subcultured every 3–6 months. However, because of genetic instability of certain strains (Pfeifer et al., 1981), routine subculturing is not recommended, and long-term storage by freezing or drying is preferred.

The vast majority of described species may be dried under vacuum. A concentrated cell suspension (20 μ l) is dropped onto a predried, sterile skimmed milk plug, which rapidly absorbs excess moisture. The tube is then placed under vacuum. The combined effect of high salinity and binding of water to the skimmed milk plug appears to have a protective function. This method is used by the Deutsche Sammlung von Mikroorganismen und Zellkulturen mbH (DSMZ) for routine preservation of members of the *Halobacteriales* (Tindall, 1991; Tindall, 1992). Dried preparations are best stored at 4–8°C. Sakane et al., 1992 recommended liquid drying (L-drying, vacuum drying from the liquid state without freezing). The procedure was successfully used for the preservation of *Halobacterium salinarum*, *Haloferax volcanii*, *Haloarcula vallismortis*, *Halococcus morrhuae*, *Halorubrum saccharovorum*, and *Natronomonas pharaonis*. In this procedure, cells are suspended in 0.1 M K-phosphate buffer pH 7, containing 10% Na-glutamate, 1.5% adonitol, 2% sorbitol, 15% NaCl, and 0.05% Na-thioglycolate. Portions of 0.1 ml suspension in sterile ampoules provided with cottonwool plugs are dried in vacuo, and then the ampoules are sealed. A detailed protocol was presented by Dyall-Smith, 1999.

Storage in a frozen state presents another option for the preservation of cultures of halophilic Archaea. A glass capillary method is used by the DSMZ for freezing cells in liquid nitrogen. As described by Tindall, 1992, cell pellets of late exponential growth phase cells are collected by low-speed centrifugation and suspended in fresh growth medium containing 5% (w/v) dimethylsulfoxide. Sterile glass capillaries are filled with the suspension and stored in liquid nitrogen. Cells also may be stored at –60 to –80°C in 10% or 20% glycerol (w/v) (Hochstein, 1988; Jones et al., 1984). When resuspended in growth medium for revival of the cultures the medium should be properly buffered for those strains that produce acids from glycerol. Dyall-Smith, 1999 has provided detailed protocols.

Physiology

The *Halobacteriales* are aerobic heterotrophic prokaryotes. Aerobic degradation of carbon sources is based on the tricarboxylic acid cycle, if necessary in combination with the glyoxylate cycle, and respiratory electron transport involving a chain of cytochromes. All the enzymes of the tricarboxylic acid cycle have been demonstrated in *Halobacterium salinarum* (Aitken and Brown, 1969), and NMR spectroscopy following ¹³C-labeling showed very rapid cycling of carbon through the pathway (Ghosh and Sonawat,

1998). Enzymes of the glyoxylate cycle are present as well in *Halobacterium salinarum* (Aitken and Brown, 1969), and a functional glyoxylate cycle has been demonstrated in *Haloferax volcanii* (Serrano et al., 1998) and in *Natronococcus occultus* (Kevbrina and Plakunov, 1992).

A variety of respiratory cytochromes and other electron transport proteins involved in respiration has been characterized in different members of the *Halobacteriales*. In *Halobacterium salinarum*, *b*-type cytochromes are present in the largest quantities, and four different *b*-type cytochromes have been identified (Hallberg-Gradin and Colmsjö, 1989). Low levels of a *c*-type cytochrome and cytochrome *o* and *a*₁ are present as well (Cheah, 1970; Hallberg and Baltcheffsky, 1979; Hallberg and Baltcheffsky, 1981).

An interesting blue copper-containing redox protein has been described as a peripheral membrane protein in *Natronomonas pharaonis* and was termed halocyanin (Scharf and Engelhard, 1993). The respiratory electron transport chain of *Natronomonas* thus consists of a cytoplasmic cytochrome *c* (–142 mV), a membrane-bound cytochrome *bc* (redox potentials of the heme B and heme C groups –117 and –44 mV, respectively), the copper heme B protein halocyanin (+128 mV), and the membrane-bound cytochrome *ba*₃ with a heme A_s group (+358 mV) (Scharf et al., 1997).

Though *Halobacterium salinarum*, the type species of the type genus of the *Halobacteriaceae*, is unable to grow on sugars, different carbohydrates can be used by a variety of other species. Carbohydrate utilization was first demonstrated in *Halorubrum saccharovorum* (Tomlinson and Hochstein, 1972a; Tomlinson and Hochstein, 1976). The glycolytic Embden-Meyerhof pathway is not functional in the *Halobacteriaceae* as hexokinase and phosphofructokinase activities are low and strongly salt-inhibited (Rawal et al., 1988a). Instead, breakdown of glucose by *Halorubrum saccharovorum* and probably other members of the group follows a modified Entner-Doudoroff pathway in which the phosphorylation step is postponed. Glucose is oxidized by gluconate to 2-keto-3-deoxygluconate and then phosphorylated to 2-keto-3-deoxy-6-phosphogluconate, which is split into pyruvate and glyceraldehyde-3-phosphate (Tomlinson et al., 1974).

Use of carbohydrates is often associated with the production of acids, as oxidation of such substrates is incomplete (Hochstein, 1978; Hochstein, 1988, see also Tables 2–6). When grown on glucose, *Halorubrum saccharovorum* was shown to excrete acetate and pyruvate (Tomlinson and Hochstein, 1972b; Tomlinson et al., 1978). On other sugars, aldonic acids may be formed: galac-

tonic acid is produced by *Halorubrum saccharovororum* in the presence of galactose (Hochstein et al., 1976), lactobionic acid is made from lactose (Tomlinson et al., 1978), and also arabinose, ribose, and xylose are oxidized to the corresponding aldonic acids (Hochstein, 1978; Hochstein, 1988). Acetate, pyruvate, and D-lactate were identified in cultures of a variety of *Haloferax* and *Haloarcula* species grown in the presence of glycerol (Oren and Gurevich, 1994).

Although the Embden-Meyerhof pathway is generally not involved in the degradation of sugars in the halophilic Archaea, many of the enzymes of the pathway are present and function in gluconeogenesis (Sonawat et al., 1990). The fructose-1,6-bisphosphate aldolase involved in the pathway has been characterized (Krishnan and Altekar, 1991). When grown on fructose, *Haloarcula vallismortis* may use the pathway also for dissimilatory purposes, degrading fructose via fructose-1-phosphate, which is then further phosphorylated to fructose-1,6-bisphosphate by an ATP-dependent fructose 1-phosphotransferase (Altekar and Rangaswamy, 1990).

In addition to the enzymes of the modified Entner-Doudoroff pathway and gluconeogenesis, the methylglyoxal bypass (dihydroxyacetone phosphate \rightarrow methylglyoxal \rightarrow D-lactate) may be operative in the halophilic Archaea. Methylglyoxal synthase, the first enzyme of the pathway, was found in all species tested except *Halobacterium salinarum*, whereas glyoxalase I was found in all species tested (Oren and Gurevich, 1995).

Glycerol, produced as an osmotic solute by the halophilic green alga *Dunaliella*, may be one of the main substrates supporting growth of halophilic Archaea in salt lakes (Borowitzka, 1981; Javor, 1984; Oren, 1993a; Oren, 1995a; Oren and Shilo, 1985). Production of D-lactate, acetate and pyruvate from glycerol also could be demonstrated in natural communities of halophilic Archaea from the Dead Sea and from saltern crystallization ponds amended with micromolar concentrations of glycerol (Oren and Gurevich, 1994). The acetate was utilized very poorly by the community, and acetate turnover-times in hypersaline environments were shown to be very long—in the order of weeks to months (Oren, 1995b). In a hypersaline cyanobacterial mat, red halophilic Archaea were found (including *Haloarcula japonica* and *Halorubrum distributum*), and it was suggested that these organisms primarily used tricarboxylic-acid-cycle intermediates excreted by *Microcoleus chthonoplastes*, the main component of the cyanobacterial mat (Zvyagintseva et al., 1995a).

In addition to simple substrates such as amino acids, sugars, and organic acids, certain poly-

meric substances can be degraded by halophilic Archaea. Many species of *Halobacteriales* produce exoenzymes such as proteases, lipases, DNases and amylases (see also Tables 2–6).

A number of unusual substrates such as aliphatic and aromatic hydrocarbons is used at least by certain representatives of the group. Red halophilic Archaea were isolated from a salt marsh in the south of France from an enrichment culture with the C₂₀ hydrocarbon eicosane (Bertrand et al., 1990). One of the isolates degraded a wide variety of compounds, including even- and odd-carbon-number saturated hydrocarbons (tetradecane, hexadecane, eicosane, heneicosane), saturated isoprenoid alkanes (pristane), aromatic hydrocarbons (acenaphthene, phenanthrene, anthracene, 9-methylanthracene), and also long-chain fatty acids such as palmitic acid. No taxonomic description of the isolate has been published as yet. Halophilic Archaea have been found in association with oilfield brines (Zvyagintseva et al., 1995b). Also, hydrocarbon-degrading halophilic Archaea (strains taxonomically close to *Halobacterium salinarum*, *Haloferax volcanii* and *Halorubrum distributum*) were isolated from hypersaline brines from an oil deposit in Tatarstan (Kulichevskaya et al., 1991). A *Haloferax* isolate obtained from soil contaminated with oil brine was shown to grow on different aromatic compounds, including benzoate, cinnamate, and 3-phenylpropionate, as sole carbon and energy sources (Emerson et al., 1994). Degradation of 3-phenylpropionate involves a gentisate 1,2-dioxygenase (Fu and Oriel, 1998; Fu and Oriel, 1999).

In view of the fact that the *Halobacteriales* are all strictly heterotrophic bacteria, the finding of ribulose-1,5-bisphosphate carboxylase (RuBisCo) activity in certain *Haloferax* and *Haloarcula* species came as a surprise (Altekar and Rajagopalan, 1990; Rawal et al., 1988b). The RuBisCo of *Haloferax mediterranei* was characterized in further detail. The enzyme is a hexadecamer of 500 kDa apparent molecular mass, consisting of 54 and 14 kDa subunits (Rajagopalan and Altekar, 1994). It cross-reacts with anti-spinach RuBisCo antibodies (Altekar and Rajagopalan, 1990). In contrast to most other proteins of halophilic Archaea the *Haloferax* RuBisCo does not possess an excess of acidic amino acid residues (Rajagopalan and Altekar, 1994). Additional enzymes of the Calvin cycle, including phosphoribulokinase, have been identified in RuBisCo-containing halophilic Archaea (Rawal et al., 1988a), but autotrophic growth was never demonstrated. A correlation has been suggested between the presence of RuBisCo activity and the ability to accumulate poly- β -hydroxyalkanoate as storage polymer, shown in *Haloferax mediterranei* (Lillo and

Rodriguez-Valera, 1990; Rodriguez-Valera and Lillo, 1992), *Haloferax volcanii*, and *Haloarcula marismortui* (Kirk and Ginzburg, 1972). However, the nature of the connection between the two phenomena remains unclear. No information is available as yet on the contribution of CO₂ fixed via the RuBisCo to the total carbon assimilated during growth.

Additional modes of CO₂ fixation, not involving RuBisCo, have been indicated in different members of the halophilic Archaea. *Halobacterium salinarum* cells containing bacteriorhodopsin showed a light-induced stimulation of CO₂ uptake (Danon and Caplan, 1977). The process was suggested to involve a reductive carboxylation of propionate (Danon and Caplan, 1977), biosynthesis of glycine (Javor, 1988), or biosynthesis of pyruvate (Rajagopalan and Altekari, 1991). Light-stimulated CO₂ incorporation by members of the *Halobacteriales* was observed also in a bacteriorhodopsin-containing community of halophilic Archaea (probably involving *Halorubrum sodomense*) in the Dead Sea (Oren, 1983b).

Anaerobic metabolism

Due to its low solubility in salt-saturated brines, oxygen may easily become a limiting factor for development of halophilic Archaea. A few representatives of the group may overcome oxygen limitation by producing gas vesicles, enabling them to float toward the air-water interface. In addition, many halophilic Archaea are able to grow anaerobically. Modes of anaerobic growth documented within the *Halobacteriales* include the use of alternative electron acceptors such as nitrate, dimethylsulfoxide, trimethylamine N-oxide or fumarate, fermentation of arginine, and light-driven anaerobic growth in cells containing bacteriorhodopsin.

The ability to reduce nitrate is widespread among the members of the *Halobacteriales* (see also Tables 2–6). A few species (e.g., *Haloferax denitrificans*, several members of the genus *Haloarcula*, *Halogeometricum borinquense*) are able to grow anaerobically using nitrate as electron acceptor. Nitrate is then reduced to gaseous products, generally N₂, but also N₂O formation has been observed in several species (Hochstein and Tomlinson, 1985; Mancinelli and Hochstein, 1986; Tomlinson et al., 1986). The dissimilatory nitrate reductases of *Haloferax denitrificans* and *Haloferax mediterranei* have been characterized (Hochstein, 1991). The ecological relevance of anaerobic growth on nitrate has never been ascertained. In view of the low concentrations of nitrate generally encountered in hypersaline brines and the apparent lack of regeneration of nitrate by nitrification at high salt concentra-

tions, the process can be expected to occur only to a limited extent in nature (Oren, 1994a).

Other alternative electron acceptors for respiration in many species are dimethylsulfoxide (DMSO), trimethylamine N-oxide (TMAO), and fumarate. Reduction of DMSO and TMAO was found to be coupled with growth in several species. *Halobacterium salinarum*, *Haloferax mediterranei*, *Haloarcula marismortui*, and *Haloarcula vallismortis* grew anaerobically in the presence of DMSO or TMAO, but *Haloferax volcanii* grew anaerobically in the presence of DMSO but not TMAO (Oren and Trüper, 1990). The ecological importance of DMSO reduction is not clear. However, TMAO may be available as an electron acceptor in salted fish, being present in often high concentrations within the fish tissues as an osmotic solute. Fumarate-driven anaerobic growth was reported in certain *Halobacterium salinarum* strains, in *Haloferax denitrificans*, and in *Haloferax volcanii* (Oren, 1991). Likewise, elemental sulfur and thiosulfate have been suggested to serve as potential electron acceptors (Tindall and Trüper, 1986), but little information is available on the nature of the process.

Fermentation of L-arginine to citrulline can drive anaerobic growth in *Halobacterium salinarum* (Hartmann et al., 1980; Oesterhelt, 1982). An in-depth genetic analysis of the genes involved in the arginine fermentation pathway has been performed (Bickel-Sandkötter et al., 1996; Ruepp and Soppa, 1996). Anaerobic growth on arginine does not seem to be widespread among the Archaea; a wide variety of neutrophilic strains tested belonging to genera other than *Halobacterium* gave negative results (Oren, 1994b; Oren and Litchfield, 1999). As a result, a specific enrichment procedure for members of the genus *Halobacterium* was developed, based on their ability to grow anaerobically in the presence of L-arginine (Oren and Litchfield, 1999).

Light can be used as an energy source to drive anaerobic growth in *Halobacterium salinarum*, provided the cells contain the light-driven proton pump, bacteriorhodopsin (Hartmann et al., 1980; Oesterhelt, 1982; Oesterhelt and Krippahl, 1983). As the biosynthesis of bacteriorhodopsin from β -carotene is oxygen-dependent, either trace concentrations of oxygen should be present or retinal or retinaloxime should be supplied to the medium to enable sustained light-driven anaerobic growth (Oesterhelt and Krippahl, 1983).

OSMOTIC ADAPTATION To cope with the high osmotic pressure of their hypersaline medium, the cytoplasm of the halophilic Archaea of the order *Halobacteriales* contains molar concentra-

tions of ions, especially K^+ and Cl^- , with often considerable concentrations of Na^+ being reported as well. This strategy of “salt-in” to balance “salt-out,” though it adapts the cellular components to function in the presence of high ionic concentrations, is found in only a small group of obligatory anaerobic halophilic Bacteria (order Haloanaerobiales, families Haloanaerobiaceae and Halobacteroidaceae). All other halophilic microorganisms known, prokaryotic as well as eukaryotic, use organic solutes to balance their cytoplasm osmotically with the salt concentrations found in their environment. The mechanisms enabling the establishment of the huge potassium concentration gradient over the cytoplasmic membrane and also the often large sodium gradient present, as well as the special adaptations of the intracellular enzymatic machinery to the presence of high ionic concentrations, have been described in Life at High Salt Concentrations in Volume 2.

It was recently shown that some haloalkaliphilic Archaea, in addition to possessing high intracellular salt concentrations, may contain an organic osmotic solute as well: 2-sulfotrehalose. When grown in defined media lacking yeast extract, this novel compound was found inside *Natronococcus occultus* at concentrations of up to 0.9 M. However, in rich media containing yeast extract the use of inorganic ions is preferred over synthesis of 2-sulfotrehalose (Desmarais et al., 1997). The role of 2-sulfotrehalose accumulation by haloalkaliphilic Archaea is still far from clear.

Genetics

During the past 15 years considerable progress has been made in the study of the genetics of the *Halobacteriales*. Mutant strains have been characterized, and different types of gene transfer systems have been developed, based on cell fusion, transformation, or transfection. Reviews on the genetics of the group were presented by Doolittle et al., 1992, Pfeifer, 1988, and Schalkwyk, 1993. A wealth of technical information, including detailed protocols for genetic experiments with the halophilic Archaea, is available online (Dyall-Smith, 1999).

Chromosomes and plasmids

It was reported as early as 1963 that, during buoyant density centrifugation in $CsCl$ gradients, the DNA of many species of the *Halobacteriales* is resolved into a major (“FI DNA”) band and a minor (“FII DNA” or “satellite DNA”) band of lower G+C content (Joshi et al., 1963). The FII fraction accounts for 11–36% of the total DNA

(Joshi et al., 1963; Moore and McCarthy, 1969). Alternative methods for the determination of the G+C composition of the DNA, such as T_m and HPLC techniques, do not provide information on whether two types of DNA are present.

The more A+T-rich FII DNA consists of a heterogeneous collection of covalently closed circular DNA (cccDNA) fractions, but there also may be “islands” of FII DNA within the chromosome (Pfeifer, 1988). The FII islands on the chromosome are often the sites of insertion sequences, which are present in high numbers in *Halobacterium salinarum*, and are responsible for the high frequency of spontaneous mutations found in this species. The genome of *Halobacterium salinarum* (“halobium”) NRC-1 contains a variety of transposable elements that give rise to frequent DNA rearrangements (DasSarma, 1993; Ng et al., 1998).

In *Halobacterium salinarum* (“halobium”) NRC817, cccDNA is a heterogeneous collection of molecules ranging in size from 60 to 180 kb. The main species was termed pHH1 (150 kb) and is present in 6–8 copies per genome (Pfeifer, 1988). Large plasmids (“megaplasmids”) are found in many representatives of the *Halobacteriales* (Gutiérrez et al., 1986; Ng et al., 1998). Many strains have between 2 and 6 large plasmids with sizes between 150 and 450 kb (Gutiérrez et al., 1986). A large dynamic replicon of 191 kb from *Halobacterium salinarum* (“halobium”) NRC-1 that can be designated either as a megaplasmid or as a minichromosome was recently characterized (Ng et al., 1998). In addition to major cccDNAs, minor cccDNAs of variable sizes and quantities are present in most strains (Pfeifer, 1988). Detailed information on the structure of a number of plasmids from halophilic Archaea was supplied by DasSarma, 1995.

The function of the plasmids in the halophilic Archaea is largely unknown. However, in certain cases the property of gas vesicle production may be plasmid-linked (Simon, 1978; Weidinger et al., 1979).

Organization of the genome

The isolation of mutants, both spontaneous and induced, has opened the way toward the elucidation of the genomic organization in a number of species of the *Halobacteriales*.

In *Halobacterium salinarum*, phenotypic markers such as changes in pigmentation and colony appearance have proved useful in genetic analyses. Properties such as the red pigmentation caused by presence of bacterioruberins, presence of purple membrane with bacteriorhodopsin, and content of gas vesicles were shown to mutate spontaneously with a high frequency (10^{-2} for gas vesicle formation, 10^{-4} for the production of bac-

terioruberin and purple membrane) (Pfeifer, 1988).

The genome of *Halobacterium salinarum* contains many repeated sequences, which are highly mobile and are arranged in both clustered and dispersed fashion within the chromosome (Sapienza and Doolittle, 1982). These sequences represent insertion sequences, which by spontaneous insertions, deletions and rearrangements in the genome are responsible for the high mutation frequencies (Charlebois and DasSarma, 1995; Pfeifer, 1986). The genomic instability of *Halobacterium salinarum* seems to be unique and is not a common feature of all halophilic Archaea (Pfeifer, 1988).

Mutagenesis can be induced chemically also, and procedures such as mutagenesis by ethyl methanesulfonate or N-methyl-N'-nitro-N-nitrosoguanidine (Bonelo et al., 1984b; Charlebois et al., 1989) were proven effective for the isolation of auxotrophic mutants.

Analysis of large numbers of mutants has shown that many metabolic pathways are organized in operons. Thus, all of the 29 tryptophan auxotrophic alleles characterized in *Haloferax volcanii* map are in one of two positions in the genome. On the other hand, some other biosynthetic pathways controlled by operons in *Escherichia coli* are probably not organized in operons in *Haloferax volcanii*: 23 histidine auxotrophic mutants mapped in six unlinked positions (Doolittle et al., 1992).

Introns have been found in several genes. Thus, the tryptophan (trp) tRNA gene of *Haloferax volcanii* has an intervening sequence of 105 bp. Another unusually structured gene is the 5S rRNA of *Halococcus morrhuae*, which is abnormally long (231 bp, containing a 108 bp insertion in the putative helix 5) (Luehrsen et al., 1981).

No complete genomic sequences have been published for any of the members of the *Halobacteriaceae* at the time of writing (June 1999), but considerable information on the genome structure is already available for several representatives of the group (Charlebois, 1999). Physical maps of the *Haloferax volcanii* and *Halobacterium salinarum* chromosomes have been constructed (Charlebois, 1995a; Charlebois, 1995b; Charlebois et al., 1989; Charlebois et al., 1991; Doolittle et al., 1992). In the case of *Halobacterium salinarum* genetic studies are complicated because of the instability of the genome, which undergoes spontaneous rearrangements at a high frequency (Pfeifer, 1988; Pfeifer et al., 1981). However, other species such as *Haloferax volcanii* and *Haloferax mediterranei* possess stable genomes, more amenable to analysis (López-Garcá et al., 1995). For *Haloferax volcanii*, a large number of ethyl methanesulfonate-induced auxotrophic mutants has been located (Cohen

et al., 1992). The total size of the genome is 3.7 million bp, as appears from the physical map: 2,920 kbp on the chromosome, and plasmids have 690, 442, 86 and 6.4 kbp (Charlebois et al., 1991; Doolittle et al., 1992).

Genetic manipulation of halophilic Archaea

A number of techniques for the genetic manipulation of members of the *Halobacteriales* are now available. These include gene transfer by mating (Mevarech and Werczberger, 1985; Ortenberg et al., 1999; Rosenshine et al., 1989) and transformation with native plasmids, with chromosomal DNA, with shuttle vectors grown in *Haloferax volcanii* or in *Escherichia coli*, with cosmid DNA from *Escherichia coli*, with restriction fragments of cosmid DNA, and with double- and single-stranded M13 sequencing templates (Doolittle et al., 1992). An overview of the techniques, including detailed laboratory protocols, was given by Dyall-Smith, 1999.

Studies with auxotrophic mutants of *Haloferax volcanii* showed that cells can exchange genetic information by mating, following formation of cytoplasmic bridges. As a result, mixing of different auxotrophs led to the formation of prototrophic recombinants (Mevarech and Werczberger, 1985; Ortenberg et al., 1999; Rosenshine et al., 1989). Direct contact of the cells is necessary, to be achieved, e.g., by filtration on nitrocellulose filters or within cell pellets during centrifugation. Electron micrographs show that *Haloferax volcanii* cells grown in colonies are often connected by cytoplasmic bridges (Mullakhanbhai and Larsen, 1975; see also Fig. 4a). This phenomenon may be related to the cell fusion during mating. Both plasmid and chromosomal DNA may cross in both directions. Plasmids and chromosomal markers are transferred in tight linkage and at similar frequencies (Ortenberg et al., 1999; Tchelet and Mevarech, 1994). The process is not inhibited by DNase (Rosenhine and Mevarech, 1991). In addition, unidirectional interspecies gene transfer between *Haloferax volcanii* and *Haloferax mediterranei* has been demonstrated, involving fusion of cells and transfer of plasmids. Thus, *Haloferax mediterranei* cells were obtained that carry the *Haloferax volcanii* hydroxymethylglutaryl-CoA reductase gene that bestows resistance to mevinolin (Tchelet and Mevarech, 1994).

Transformation was first shown in *Haloferax volcanii*, using plasmid pHV2 (Charlebois et al., 1987). Transformation can be achieved by addition of DNA and low molecular weight polyethylene glycol to spheroplasts formed upon removal of magnesium and other divalent cations from the medium by EDTA. The sphero-

plasts are subsequently regenerated on agar plates (Dyall-Smith, 1999). Such transformation has been achieved thus far in *Haloferax volcanii*, *Halobacterium salinarum*, *Haloarcula hispanica*, and *Haloarcula vallismortis* (Cline et al., 1989a; Cline et al., 1989b; Cline et al., 1995; Doolittle et al., 1992).

Different plasmid shuttle vectors carrying one or more selectable markers have been developed for genetic studies of halophilic Archaea, such as gene disruption experiments and construction of mutant strains (Cline and Doolittle 1992; Das-Sarma, 1995a; Doolittle et al., 1992; Dyall-Smith and Doolittle, 1994; Holmes and Dyall-Smith, 1990; Holmes et al., 1991; Holmes et al., 1994; Lam and Doolittle, 1989). Transposon mutagenesis has been achieved in *Haloarcula hispanica*, using a transposon based on the ISH₂8-insertion sequence from *Halobacterium salinarum* and the mevinolin-resistance marker of *Haloferax volcanii* (Dyall-Smith and Doolittle, 1994). Transfection was shown as early as 1987, when it was demonstrated that *Halobacterium salinarum* spheroplasts can be transfected with DNA from its bacteriophage Φ H (Cline and Doolittle, 1987).

The recent cloning and characterization of the β -galactosidase gene *bgaH* of "*Haloferax alkaliantei*" (Holmes and Dyall-Smith, 1999; Holmes et al., 1997) promises its future use as a reporter gene in gene expression studies of halophilic Archaea, similar to the use of the *lacZ* gene in *Escherichia coli*. The gene can be transferred to *Haloferax volcanii* (β -galactosidase-negative) using shuttle plasmid pMDS20 (Holmes et al., 1994).

Ecology

Halophilic Archaea of the order *Halobacteriales* can be found in a wide variety of hypersaline ecosystems, and they often occur there in very high densities. In salt lakes such as the Great Salt Lake, the Dead Sea, and saltern crystallizer ponds, numbers of 10^7 to 10^8 cells per ml and higher are not unusual (Borowitzka, 1981; Javor, 1983; Javor, 1989; Oren, 1983c; Oren, 1990b; Oren, 1994a; Post, 1977; Post, 1981). Owing to the bright red, orange, or purple coloration of most representatives of the group and to the often extremely high community densities (among other factors the result of lack of predators able to thrive at these extremely high salt concentrations), often the presence of the dense communities of halophilic Archaea in hypersaline environments can be observed with the unaided eye. Lakes with salt concentrations approaching saturation may show red hues, such as documented for the north arm of the Great

Salt Lake (Post, 1977; Post, 1981), the Dead Sea (Arahal et al., 1996; Kaplan and Friedmann, 1970; Oren, 1983c; Oren et al., 1988; Oren, 1993a) and hypersaline alkaline lakes such as Lake Magadi, Kenya (Grant and Tindall, 1986). Red colored brines are also typically present during the final stages of the evaporation of sea water in solar saltern ponds (Borowitzka, 1981; Javor, 1989; Jones et al., 1981; Oren, 1994a). Though the presence of the β -carotene-rich green halophilic alga *Dunaliella salina* also may contribute to the red coloration of the brines, the red halophilic Archaea generally are responsible for most of the color of the saltern brines (Oren and Dubinsky, 1994; Oren et al., 1992).

Considerable differences exist between the different genera and species within the *Halobacteriaceae* with respect to salt requirement and tolerance (see also Tables 2–6). In contrast to types such as *Halobacterium salinarum*, which will not grow below 3 M NaCl, many representatives, especially those belonging to the genus *Haloferax*, thrive at much lower salt concentrations. Thus, *Haloferax volcanii*, an organism isolated from the Dead Sea, was described as a moderate rather than an extreme halophile, growing optimally at about 2.5 M NaCl (Mullakhanbhai and Larsen, 1975). *Haloferax mediterranei* can grow down to 1.7 M NaCl and survive below 0.85 M (D'Souza et al., 1997). Accordingly, in a study of the microbial communities in saltern ponds of different salinities, *Haloferax* species were recovered with the highest frequency from ponds of intermediate salinities (Rodriguez-Valera et al., 1985).

The concentration of divalent cations, especially magnesium and calcium, in the environment is of considerable ecological importance. Thus, the Dead Sea is dominated by divalent cations (presently around 1.9 M Mg²⁺ and 0.4 M Ca²⁺, in addition to about 1.7 M Na⁺ and 0.14 M K⁺). Halophilic Archaea isolated from the Dead Sea are characterized by a relatively low requirement for Na⁺ and an extraordinarily high tolerance toward and often also a requirement for high Mg²⁺ concentrations, such as was shown for *Haloferax volcanii* (Mullakhanbhai and Larsen, 1975), *Halorubrum sodomense* (Oren, 1983a), and *Halobaculum gomorrense* (Oren et al., 1995). Strains tolerant to high magnesium concentrations are not limited in their distribution to the Dead Sea, but can be isolated from thalassohaline environments such as saltern crystallizer ponds (Javor, 1983; Javor, 1984). In this respect it should be noted that as a result of the precipitation of halite in these ponds highly increased magnesium concentrations may be encountered. Most halophilic Archaea that live in thalassohaline environments of neutral pH also require relatively high concentrations of

Mg²⁺ as compared to most other prokaryotes, and many species need concentrations of at least 50–100 mM Mg²⁺ for optimal growth. Suboptimal magnesium concentrations often cause loss of the native cell shape and formation of coccoid cells which may continue to grow at suboptimal rates (Brown and Gibbons, 1995) or lose their viability altogether (Cohen et al., 1983). The specific requirements for and tolerances toward total ionic strength and divalent cations in different members of the *Halobacteriales* have been compared by Edgerton and Brimblecombe, 1981, defining the growth boundaries of a thalassohaline strain such as *Halobacterium salinarum* with those of the Dead Sea isolate *Haloferax volcanii*. The approach used can be adapted easily to the characterization of the ecological niches of other members of the group.

A number of alkaliphilic halophilic archaeal species have been isolated from hypersaline soda lakes: *Halorubrum vacuolatum* (Mwatha and Grant, 1993), *Natronomonas pharaonis* (Soliman and Trüper, 1982), *Natrialba magadii*, *Natronobacterium gregoryi*, *Natronococcus occultus* (Tindall et al., 1984), and *Natronococcus amylolyticus* (Kanai et al., 1995). These species grow optimally at pH values between 9 and 10 and are unable to grow at neutral pH. In accordance with the low solubility of the divalent cations Mg²⁺ and Ca²⁺ at high pH, the alkaliphilic halophiles do not require high magnesium concentrations to grow. Optimal growth is achieved at Mg²⁺ concentrations as low as 1 mM, and magnesium concentrations above 10 mM might be inhibitory (Tindall et al., 1980).

At the high salt concentrations required for the growth of the *Halobacteriales* predators are generally absent. Protozoa rarely occur above 20–25% salt, and they were never shown to contribute much to the reduction of the community sizes of halophilic Archaea in nature. However, lysis by bacteriophages may be an important factor in the regulation of the community sizes of halophilic Archaea in their natural environments. Bacteriophages have been shown to attack *Halobacterium salinarum* (Daniels and Wais, 1990; Torsvik and Dundas, 1974; Wais et al., 1975) and other species (Bath and Dyall-Smith, 1998; Nuttall and Dyall-Smith, 1993b). Generally these phages contain DNA only, but phage Φ Ch1 of the alkaliphilic *Natrialba magadii* contains both DNA and RNA (Witte et al., 1997). Similarly to their hosts, the bacteriophages of the halophilic Archaea require high NaCl concentrations to maintain structural integrity. Both lysogenic and virulent phages occur (Pfeifer, 1988). The possible importance of bacteriophages in controlling the community sizes of the *Halobacteriaceae* in hypersaline water bodies appears from the high number of virus-like particles—one to two

orders higher than the number of bacteria present—that can be observed by electron microscopic examination of brines from saltern crystallizer ponds (Guixa-Boixareu et al., 1996) and the Dead Sea (Oren et al., 1997c). A study of bacteriophages in a brine pool by Wais and Daniels, 1985 showed that lysis of halophilic Archaea by bacteriophages may be triggered by a decrease in water salinity as a result of dilution with rain water. Halophilic phages have been implicated also as the possible cause of sudden drops in the community size of halophilic Archaea in the Dead Sea (Oren et al., 1997c).

Different species of the *Halobacteriaceae* may compete for nutrients and other resources by excreting halophilic bacteriocins, termed “halocins,” protein antibiotics that inhibit the growth of other related species (Meseguer and Rodriguez-Valera, 1986; Rodriguez-Valera et al., 1982). Halocin production appears to be widespread among representatives of the group (Meseguer et al., 1986; Torreblanca et al., 1994). Different modes of action have been suggested for different halocins, and the information presently available has recently been summarized by Shand et al., 1999. Most known halocins act on the cell membrane of the sensitive strains (Meseguer et al., 1991). Halocin H4, excreted by *Haloferax mediterranei*, causes membrane permeability changes and ionic imbalance in *Halobacterium salinarum* (Meseguer and Rodriguez-Valera, 1986). Although the ability to excrete halocins may be expected to have considerable ecological advantage, no data are available as yet that prove that halocins are excreted by natural communities of halophilic Archaea in concentrations sufficient to inhibit the development of competitor strains, thus substantiating their ecological role.

The niche of the halophilic Archaea of the order *Halobacteriales* in nature is quite distinct from that of the halophilic or halotolerant aerobic Bacteria. A number of known Bacteria (e.g. *Halomonas elongata* and other *Halomonas* species) are able to grow at salt concentrations as high as those required by the Archaea. However, in environments with salt concentrations above 20–25% halophilic Bacteria never seem to occur in high numbers, and they are outcompeted by the Archaea. Competition experiments in the laboratory showed that in addition to salinity, temperature is a key factor determining the outcome of the competition, higher temperatures favoring the development of Archaea (Rodriguez-Valera et al., 1980b). The dominance of the halophilic Archaea in saltern ponds of salinities exceeding 250 g/liter was demonstrated by measuring heterotrophic activities in the presence of specific inhibitors such as low concentrations of bile salts, which cause lysis of the

halophilic Archaea, or specific antibiotics, which inhibit either one of the groups. Using this technique little overlap was found between the salinity range in which halophilic Bacteria were responsible for the heterotrophic activity (up to about 200–250 g/liter salt) and the higher salinity range in which the activity could be attributed to the *Halobacteriales* (Oren, 1990b; Oren, 1990c). Finally, molecular characterization of the microbial communities in saltern ponds of different salt concentrations in Spain, involving a study of rDNA restriction-fragment length polymorphism of PCR-amplified 16S rDNA, showed a dominance of halophilic Archaea in the crystallizer ponds. However, already at 133 g/liter salt, archaeal 16S rDNA sequences were different from those found between 218 and 308 g/liter salinity (Martinez-Murcia et al., 1995b), suggesting that a yet-to-be-characterized specialized group of halophilic Archaea may be present at the lower salinity range.

Applications

The halophilic Archaea of the order *Halobacteriales* have a number of useful applications, and potential new applications in biotechnological processes are being investigated (Galinski and Tindall, 1992; Rodriguez-Valera, 1992; Ventosa and Nieto, 1995).

The positive effect of the presence of dense communities of red halophilic Archaea in saltern crystallizer ponds has been recognized for a long time. By trapping solar radiation, they raise the temperature of the brine and the rate of evaporation, thereby increasing salt production (Davis, 1974; Javor, 1989). To improve salt production in salterns that do not develop a sufficiently dense archaeal community, fertilization with nutrients such as proteose-peptone and tryptone has been suggested to increase the red color of the ponds (Jones et al., 1981).

Production of fermented fish sauce in the Far East (e.g., nam pla in Thailand) involves participation of halophilic Archaea. The product is traditionally made by adding two parts of fish and one part marine salts. The mixture is covered with concentrated brine (4.4–5.1 M NaCl) and left to ferment for about a year. Red halophilic Archaea (identified as *Halobacterium* and *Halo-coccus*) reach their maximum density in the liquor after 3 weeks and persist throughout the fermentation period. The halobacterial proteases probably take part in the fermentation process (Thongthai and Siriwongpairat, 1990; Thongthai and Suntinalert, 1991; Thongthai et al., 1992).

Different species of halophilic Archaea synthesize potentially useful products such as bacteriorhodopsin, exopolysaccharides, poly-

β-hydroxyalkanoate, and others. Halophilic Archaea have distinct advantages in biotechnological processes as cultivation is relatively easy, risk of contamination is minimal, and culture-size can be upscaled to the use of large fermentors (e.g., 70-liter cultures were grown by Kushner, 1966). However, because of the low solubility of gases in concentrated brines the supply of sufficient amounts of oxygen may cause some problems (Shand and Perez, 1999). In addition, the aggressive nature of the salts should be taken into account when planning the construction of large fermenters with metal parts exposed to the medium.

Bacteriorhodopsin, the light-driven proton pump of *Halobacterium salinarum*, has considerable biotechnological potential (Oesterhelt et al., 1991). It may be used as a biological material for information processing. Other potential uses suggested include conversion of sunlight to electricity, ATP generation, desalination of sea water, use in chemo- and biosensors, and ultrafast light detection. The photochromic effect, shifts between the purple ground state of the molecule (the “B state”) and the yellow “M state,” may be used for information storage, including holographic storage (König, 1988), and may lead to the development of powerful computer memories and processors (Birge, 1995). Bacteriorhodopsin offers many advantages since it is a very stable molecule, functioning well between 0–45°C and pH 1–11 (Chen and Birge, 1993), is easy to immobilize on solid substrates, and produces very reproducible photoelectric signals (König, 1988). Holographic bacteriorhodopsin films are suitable for the construction of computer memories enabling parallel processing, and the developing technology might lead to a new generation of computers (Hong, 1986). To turn bacteriorhodopsin into a light sensor, it is spread in a thin film sandwiched between an electrode and an electrically conductive gel. Changes in the shape of the molecule create a displacement of charge, generating an electrical signal.

The extracellular polysaccharide produced by *Haloferax* may have biotechnological potential (Antó et al., 1988; Rodriguez-Valera et al., 1991). The bacterium produces up to 3–8 g/liter of an acidic heteropolysaccharide with a high apparent viscosity at relatively low concentrations and resistance to extremes of salt concentrations, temperature, and pH. The structure of this polymer was recently elucidated (Parolis et al., 1996). *Haloferax volcanii* and *Haloferax gibbonsii* also produce exopolysaccharides (Paramonov et al., 1998; Severina et al., 1990). Such polymers may be used to modify rheological properties of aqueous systems, for viscosity stabilization as thickening agents, gelling agents and emulsifiers, and may find applications in

microbially enhanced oil recovery (Ventosa and Nieto, 1995). Here a salt-resistant surfactant is advantageous as high salinity brines are encountered often associated with oil deposits. Whole cell preparations may be used, as the lipids liberated upon lysis of halophilic Archaea may act as surfactants to improve the oil-carrying properties (Post and Al-Harjan, 1988).

Haloferax mediterranei cells may contain considerable amounts of poly- β -hydroxyalkanoate (PHA) (Fernandez-Castillo et al., 1986; Rodriguez-Valera et al., 1991) (Fig. 3b). PHA is used for the production of biodegradable plastics. Though halophilic Archaea are not yet being used commercially for PHA production, they have certain obvious advantages over an organism such as *Ralstonia eutropha*, which is already being exploited for the purpose. *Haloferax mediterranei* can be grown on a cheap substrate such as starch. Moreover, downstream processing and purification of the product should be relatively simple, as the cells are easily lysed in water (Ventosa and Nieto, 1995). Also the high genomic stability of the organism and the reduced danger of contamination are clear assets. PHA production is maximal when grown on sugars (glucose or starch) and in the presence of low phosphate concentrations (Lillo and Rodriguez-Valera, 1990; Rodriguez-Valera and Lillo, 1992). PHA production has been demonstrated in certain other halophilic Archaea as well, such as *Haloferax volcanii* and *Haloarcula marismortui* (Kirk and Ginzburg, 1972; Rajagopalan and Altekari, 1991).

A number of additional potential uses of halophilic Archaea have been suggested:

- The glycerol diether lipids may find application as a food additive, to serve as a non-caloric fat substitute (Collins, 1977; Post and Collins, 1982).

- Exoenzymes such as amylases, amyloglucosidases, proteases, and lipases that function at high salinity may be useful in biotechnological processes requiring degradation of macromolecules in the presence of high salt concentrations (Chaga et al., 1993; Ventosa and Nieto, 1995).

- Hydrocarbon degrading halophilic Archaea (Bertrand et al., 1990; Emerson et al., 1994; Kulichevskaya et al., 1991) may prove useful in the bioremediation of oil spills.

- An 84-kDa protein from *Halobacterium salinarum* has been used as an antigen to detect antibodies against the human *c-myc* oncogene product in the sera of cancer patients, and therefore the protein may be useful for the detection of certain forms of cancer (Ben-Mahrez et al., 1988; Ben-Mahrez et al., 1991).

- Site-specific endonucleases of halophilic Archaea (Schinzel and Burger, 1986) may find uses in molecular biological research.

The Methanogenic Bacteria

WILLIAM B. WHITMAN, TIMOTHY L. BOWEN AND DAVID R. BOONE

The methanogenic bacteria are a large and diverse group that is united by three features: 1) They form large quantities of methane as the major product of their energy metabolism. 2) They are strict anaerobes. 3) They are members of the domain Archaea, or archaeobacteria, (see Chapter 1) and only distantly related to the more familiar classical bacteria or eubacteria. Like the photosynthetic eubacteria, the methanogenic bacteria are related to each other primarily by their mode of energy metabolism but are very diverse with respect to their other properties.

Methanogenic bacteria obtain their energy for growth from the conversion of a limited number of substrates to methane gas. The major substrates are $H_2 + CO_2$, formate, and acetate. In addition, some other C-1 compounds such as methanol, trimethylamine, and dimethylsulfide and some alcohols such as isopropanol, isobutanol, cyclopentanol and ethanol are substrates for some methanogens. All of these substrates are converted stoichiometrically to methane. In this regard, the metabolism of the methanogens is strikingly different from that of the so-called “minimethane” producers, which are other anaerobic microorganisms that produce very small amounts of methane as a consequence of side reactions of their normal metabolism (for an overview of the minimethane producers, see Rimbault et al., 1988). Another feature that distinguishes the methanogens from the minimethane producers is that the methanogens are obligate methane-producers, that is, they only grow under conditions where methane is formed.

The list of substrates for growth of methanogens may be divided into three groups (Table 1). In the first group, the energy substrate (electron donor) is H_2 , formate, or certain alcohols and the electron acceptor is CO_2 , which is reduced to methane. The ability to utilize H_2 as an electron donor for CO_2 reduction is almost universal among methanogens. Likewise, many methanogens also utilize formate, but the ability to utilize alcohols is less common (Bleicher et al., 1989; Zellner and Winter, 1987a). Some methanogens also utilize carbon monoxide as an electron donor, but growth is very slow (Daniels et al.,

1977). CO_2 reduction is the major source of methane in certain habitats such as the rumen. In other environments, such as the sediments of freshwater lakes and certain bioreactors, only about one-third of the methane is formed from CO_2 reduction. However, this reaction is still very important for maintaining the very low concentrations of H_2 and formate typical of these anaerobic habitats and facilitating the process of interspecies electron transfer.

In the second group, the energy substrate is one of a variety of methyl-containing C-1 compounds, which can serve as substrates for a few taxa of methanogens. Usually these compounds are disproportionated. Some molecules of the substrate are oxidized to CO_2 . The electron acceptors are the remaining methyl groups, which are reduced directly to methane (Table 1). Although dimethylselenide and methane thiol also serve as substrates for methanogenesis, these substrates do not support growth (Kiene et al., 1986). Methanogenesis from C-1 compounds is common where methyl-containing C-1 compounds are abundant. In marine sediments, trimethylamine may be formed from choline, glycine betaine, or trimethylamine oxide. In the large intestine of mammals, methanol may be formed from the anaerobic transformation of the methoxy groups of pectin. Dimethylsulfide is also common in anaerobic environments where it is formed from both methionine and the osmoregulant dimethylsulfoniopropionate.

In the third group, acetate is the major source of methane, but the ability to catabolize this substrate is limited to species of *Methanosarcina* and *Methanosaeta* (“*Methanotherix*”). Acetate is present in many environments, and methane synthesis proceeds by an acetoclastic reaction, in which the methyl carbon of acetate is reduced to methane and the carboxyl carbon is oxidized to CO_2 . Methanogenesis from acetate is common in anoxic freshwater sediments where the catabolism of acetate by other anaerobes is limited by the availability of alternate electron acceptors such as sulfate or nitrate.

Methane synthesis is the major source of energy for growth of methanogens. Thus, meth-

Table 1. Reactions and standard changes in free energies for methanogenesis.^a

Reaction	$\Delta G^{\circ'}$ (kJ/mol of methane)
4 H ₂ + CO ₂ → CH ₄ + 2 H ₂ O	-135.6
4 Formate → CH ₄ + 3 CO ₂ + 2 H ₂ O	-130.1
4 2-Propanol + CO ₂ → CH ₄ + 4 Acetone + 2 H ₂ O ^b	-36.5
2 Ethanol + CO ₂ → CH ₄ + 2 Acetate ^c	-116.3
Methanol + H ₂ → CH ₄ + H ₂ O	-112.5
4 Methanol → 3 CH ₄ + CO ₂ + 2 H ₂ O	-104.9
4 Methylamine + 2 H ₂ O → 3 CH ₄ + CO ₂ + 4 NH ₄ ⁺	-75.0
2 Dimethylamine + 2 H ₂ O → 3 CH ₄ + CO ₂ + 2 NH ₄ ⁺	-73.2
4 Trimethylamine + 6 H ₂ O → 9 CH ₄ + 3 CO ₂ + 4 NH ₄ ⁺	-74.3
2 Dimethylsulfide + 2 H ₂ O → 3 CH ₄ + CO ₂ + H ₂ S	-73.8
Acetate → CH ₄ + CO ₂	-31.0

^aThe standard changes in free energies were calculated from the free energy of formation of the most abundant ionic species at neutral pH. Thus, "CO₂" is HCO₃⁻ + H⁺ and formate is HCOO⁻ + H⁺.

^bOther secondary alcohols utilized include 2-butanol, 1,3-butanediol, and cyclopentanol.

^cOther primary alcohols utilized include 1-propanol and 1-butanol. From Kiene et al. (1986), Nagle and Wolfe (1985), and Widdel (1986).

anogenesis may be viewed as a form of anaerobic respiration where CO₂, the methyl groups of C-1 compounds, or the methyl carbon of acetate is the electron acceptor. However, the standard change in free energy ($\Delta G^{\circ'}$) during most methanogenic reactions is very small, and the amount of ATP produced per mole of methane is probably close to or less than one (Table 1). In most natural habitats where the concentrations of H₂ and formate are very low, the change in free energy may even be much smaller.

The second distinctive feature of methanogens is their extreme sensitivity to oxygen. Thus, the methanogens are very strict anaerobes, and they are generally present in nature only in anoxic environments. For instance, the half-time for survival of one species of *Methanosarcina* is reported to be only 4 minutes in air-equilibrated medium (Zhilina, 1972). In part, some of the sensitivity of methanogens is probably due to the oxygen lability of many of the enzymes involved in methanogenesis. Other mechanisms are probably important as well. For instance, the methanococcal enzyme acetohydroxy acid synthase—an enzyme in the pathway of branched-chain amino acid biosynthesis—is unusually sensitive to oxygen (Xing and Whitman, 1987). Likewise, many methanogens are unable to utilize oxidized

Table 2. Distinctive features found in various members of the domain Archaea (archaeobacteria).

Capability of extreme thermophily in some groups
Lipids composed of glycerol ethers of isoprenoids and tetraethers are common
Stereochemistry of lipids is 2,3- <i>sn</i> glycerol
Cell walls composed of protein, glycoprotein, or pseudomurein; murein is absent
Antibiotic sensitivity differs from that of eubacteria
Unique modes of energy metabolism in some groups; i.e., bacteriorhodopsin-driven photosynthesis, methanogenesis

sulfur compounds. Because the most widely used sulfur source, sulfide, reacts chemically with oxygen, anaerobiosis is also required to protect the sulfur source in the medium. Paradoxically, when cultures of some species are washed and resuspended in unreduced medium in the absence of substrates, their viability is unaffected by atmospheric levels of oxygen for at least 30 hours (Kiener and Leisinger, 1983).

The third distinctive feature of the methanogens is that they are archaeobacteria (Jones et al., 1987; Woese, 1987). Other archaeobacteria include the extreme halophiles and the sulfur-dependent extreme thermophiles. Some properties the methanogens share with other archaeobacteria are listed in Table 2 and are described in more detail in subsequent sections. However, the methanogens are different from other archaeobacteria because they are abundant in environments of moderate temperature, pH, and salinity. Although some extremely halophilic or extremely thermophilic methanogens have been described, most species are found in moderate environments where they are often closely associated with anaerobic eubacteria and eukaryotes. Likewise, the methanogens are unlike other archaeobacteria in that they contain large amounts of coenzymes essential for methane synthesis (see below). Some of these, such as coenzyme F₄₂₀ and coenzyme M, may serve as distinctive biomarkers.

Habitats of Methanogenic Bacteria

Methanogenic bacteria are abundant in habitats where electron acceptors such as O₂, NO₃⁻, Fe³⁺ and SO₄²⁻ are limiting. Common habitats for methanogens are anaerobic digestors, anoxic sediments, flooded soils, and gastrointestinal tracts. Methanogens are generally absent from the water column of unstratified lakes and rivers because convection currents rapidly aerate the deep waters. However, the diffusion of O₂ between the layers of stratified lakes is often too slow to maintain oxic conditions in the lower layers. Similarly, the physical structure of sedi-

ments limits dispersive mechanisms, so deeper sediments are often anoxic and harbor methanogens. Soil environments may be divided into the vadose zone, which is not saturated with water, and the zone below the water table, which is saturated. In the vadose zone, O_2 diffusion is rapid and anoxic vadose zones are extremely rare, although anoxic microenvironments may occur. Thus, the activity of methanogens in the vadose zone is limited. O_2 diffusion through water is slower than through soil, so the water-saturated zone is often anoxic. Because air-saturated water at 20°C contains less than $0.3\text{ mM } O_2$, even small amounts of organic pollution cause groundwater to become anoxic and suitable for development of methanogenic populations.

In axenic culture, methanogenic bacteria are extremely sensitive to small amounts of O_2 . However, in natural habitats, the activities of other organisms protect methanogens in apparently oxic environments. For instance, methanogens have been isolated from large dental caries and subgingival plaque in the human mouth (Belay et al., 1988; Brusa et al., 1987). Methanogens may survive in such environments because O_2 -uptake by aerobic and euryoxic bacteria creates anoxic microenvironments.

In anoxic environments, the presence of NO_3^- , Fe^{3+} , and SO_4^{2-} inhibits methanogenesis by allowing other organisms to outcompete methanogens for reduced substrates. For instance, in the presence of sulfate, sulfate-reducing bacteria utilize H_2 at concentrations lower than the minimum concentration which can be utilized by methanogens (Kristjansson et al., 1982; Lovley, 1985). Presumably, the ability of the sulfate-reducing bacteria to outcompete the methanogens is a direct consequence of the more-positive reduction potential of SO_4^{2-} compared to that of CO_2 .

In environments with sufficient quantities of sulfate, hydrogen sulfide is the predominant reduced product, and the major fate of biodegradable organic carbon is oxidation to CO_2 . If sulfate becomes limiting, methane replaces hydrogen sulfide as the reduced product, and the organic carbon is disproportionated to CO_2 and methane. The fate of the methyl group of acetate is an indicator of whether methanogenesis is a dominant catabolic pathway in an ecosystem. If acetate is catabolized by the sulfate-reducing bacteria, CO_2 is formed from the methyl group of acetate. In a methanogenic system, acetate is catabolized by the acetoclastic reaction, which forms methane from the methyl group. Thus, methanogenic degradation of $[2-^{14}\text{C}]$ -acetate leads to $^{14}\text{CH}_4$, whereas sulfidogenic degradation leads to $^{14}\text{CO}_2$, and the ratio of these labeled gaseous products indicates

whether methanogenesis predominates (Winfrey and Zeikus, 1979). However, this test fails in some thermophilic ecosystems where acetate is oxidized to CO_2 prior to formation of methane (see below).

Sulfidogenesis normally dominates in estuarine, marine, and hypersaline sediments, where sulfate diffuses from overlying water. Beneath areas of high productivity, such as kelp forests, sulfate may be limiting in the deep organic sediments. Under these conditions, acetoclastic and H_2 - or formate-using methanogens develop. Even in surface layers where sulfate is in excess, some methanogenesis may occur from methylated compounds such as trimethylamine and dimethylsulfide. Trimethylamine is often found in marine sediments, where it is formed from betaine glycine or other related osmoprotectants which are produced by marine plants and bacteria to balance the osmolarity of their cytoplasm with that of the seawater. Trimethylamine is not easily utilized by sulfidogenic bacteria, but it is rapidly fermented by methanogens to methane, CO_2 , and ammonia. Thus, trimethylamine has been termed a "noncompetitive" substrate for methanogens. Trimethylamine-degrading methanogens from marine environments are all in the family Methanosarcinaceae, and all methanogens that have been isolated to date from hypersaline environments use trimethylamine as catabolic substrate.

Interspecies Electron Transfer and Obligate Syntrophy

Because of their limited substrate range, methanogens depend on fermentative bacteria to convert a wide range of organic compounds into methanogenic substrates. In environments where organic matter is completely degraded to methane and CO_2 , the methanogenic precursors are predominantly acetate, formate, and $H_2 + CO_2$. The organic matter is initially fermented mainly to volatile organic acids, H_2 , and CO_2 . Methanogens can directly catabolize $H_2 + CO_2$, formate, and acetate, but longer-chain volatile organic acids (with three or more carbon atoms) such as propionate and butyrate must be metabolized to one or more of these methanogenic precursors by a specialized group of microbes called syntrophs. These syntrophs form methanogenic substrates only in the presence of vanishingly low concentrations of H_2 or formate (for reviews see Boone and Mah, 1988; Wolin and Miller, 1987).

During the catabolism of sugars and amino acids, acetate production is more favorable for fermentative bacteria because an extra ATP is produced from acetyl CoA, which is derived

from pyruvate oxidation. However, if acetate is formed, the cells require an alternative mechanism to reoxidize the NADH generated during the fermentation. Many fermentative bacteria have NADH-linked hydrogenases or formate dehydrogenases, but the thermodynamics for NADH oxidation are unfavorable except at very low concentrations of H_2 or formate. For instance, the H_2 concentration must be less than about 1 μM and the formate concentration less than 100 μM for these substances to be produced from NADH. Thus, in pure cultures, H_2 or formate production from NADH is inhibited by end-product accumulation. However, when these bacteria are grown in coculture with H_2 and formate-utilizing methanogens, the concentrations of H_2 and formate remain low, and they become important products for fermentative bacteria. In such methanogenic cocultures, the fermentative bacteria produce more acetate and less reduced products such as propionate, butyrate, lactate, and ethanol. Although the fermentative bacteria can generally grow without methanogens, additional energy is obtained from phosphoroclastic acetate production when methanogens are present. Because the activities of the methanogens are not required by the fermentative bacteria, this type of interspecies electron transfer is called nonobligate interspecies electron transfer.

A second type of interspecies electron transfer cannot proceed without the activities of H_2 or formate-utilizing species. A specialized group of bacteria called obligate syntrophs oxidize compounds such as propionate, longer-chain volatile organic acids, and aromatic compounds. The obligate syntrophs must dispose of the electrons by the reduction of protons to H_2 or of CO_2 to formate. They lack alternative fermentative reactions and cannot produce other reduced organic compounds. When the concentrations of H_2 and formate are high, end-product inhibition prevents the oxidation of the syntrophic substrates. Thus, propionate and butyrate oxidation are accomplished by obligate syntrophy of fatty acid-oxidizing bacteria and methanogens. The activities of CO_2 -reducing methanogens keep the concentrations of H_2 and formate low, allowing the exergonic oxidation of fatty acids by the syntrophs.

Until recently it was assumed that H_2 is the major precursor for CO_2 -reduction to methane, although many of the CO_2 -reducing methanogens can use H_2 or formate equally well. The butyrate-oxidizing bacterium *Syntrophomonas wolfei* can produce either H_2 or formate, so the relative importance of these substances as interspecies electron carriers may depend on the enzyme kinetics of their production and degradation or the rate of diffusion between cells.

Although the diffusion coefficient of formate is only one-fifth as large as that of H_2 , the formate concentration may be one hundred times greater than that of H_2 . Under this condition, formate may be responsible for the bulk of interspecies electron transfer in some environments (Boone et al., 1989; Thiele and Zeikus, 1988).

HABITATS OF SPECIAL INTEREST. When organic matter is completely catabolized to methane and CO_2 , the major substrates of methanogens are usually acetate, formate, and $H_2 + CO_2$. However, in some environments the growth of acetate-utilizing methanogens and obligate syntrophs is too slow to maintain a large population in the system. For instance, in the rumen and colon, acetate accumulates to concentrations of 50 to 100 mM. Although this is well above the concentration required for acetate-utilizing growth of methanogens such as *Methanosarcina*, these organisms do not catabolize significant quantities of acetate because their growth rate on this substrate is too slow to maintain the population in a rapid-turnover ecosystem. However, when methylamine or methanol is present, the cell numbers of *Methanosarcina* in the rumen may reach 10^5 to 10^6 per milliliter because these substrates support a faster growth rate. Propionate and butyrate are also present in the rumen at significant concentrations, but the slowly growing propionate- and butyrate-degrading organisms are not found in abundance. In the rumen, a wide range of CO_2 -reducing methanogens may be found, including *Methanobrevibacter ruminantium*, *Methanobacterium formicicum*, and *Methanomicrobium mobile*. *Methanobrevibacter* species are the most commonly found CO_2 -reducing methanogen in nonruminant intestinal tracts. *Methanosphaera* species have also been isolated from colonic environments; they only grow by using H_2 to reduce methanol to methane.

Methanogenic bacteria form mutualistic associations with rumen, freshwater and marine ciliates and amoebae, growing as ecto- or endosymbionts. The physical associations of these microbes with protozoa may improve the efficiency of interspecies H_2 - or formate-transfer. The methanogenic partners in the endosymbioses have been classified as *Methanoplanus endosymbiosus*, *Methanobrevibacter* species, and *Methanobacterium formicicum*. It is quite possible that in some habitats such as sapropel (aquatic sludge rich in organic matter), the majority of the methanogens are involved in these symbioses (Lee et al., 1987; van Bruggen et al., 1985).

In some environments, such as hot springs and solfataras (volcanic fissures that emit steam and other gases), the predominant substrate is geo-

thermal H_2 rather than decaying organic matter. In such environments, methanogens do not rely on the activities of other organisms for provision of their substrates. The waters near these sources are often thermal as well, and thermophilic methanogens have been isolated from hot springs in Yellowstone National Park (Zeikus et al., 1980) and in Iceland (Huber et al., 1982; Lauerer et al., 1986), and from submarine thermal vents (Jones et al., 1983a).

Atmospheric Methane

At its current atmospheric concentration of 1.7 ppm, methane is the second most abundant carbon-containing gas, and its atmospheric concentration is increasing at a rate of about 1% per year (for a review, see Cicerone and Oremland, 1988). Because methane is a major greenhouse gas, its sources and atmospheric chemistry are of considerable interest. Each year, about $400\text{--}640 \times 10^{12}$ g of methane are released into the atmosphere. Estimates based upon the isotopic composition of the atmospheric methane suggest that about 74% of this methane is derived from recent microbiological activity. The total amount of methane that is produced may be far greater, and in some important habitats, microbial methane oxidation is known to be very significant. Thus, the methane-producing bacteria are an important component of the earth's carbon cycle.

The major sources of atmospheric methane include: enteric fermentations in animals; wetlands such as bogs, swamps, and rice paddies; landfills; and termites. Little methane is obtained from marine systems where competition with the sulfate-reducing bacteria and anaerobic methane-oxidizing organisms limits its production and release, respectively.

Isolation

Methanogenic bacteria are extremely sensitive to oxygen, and strict anaerobiosis and pre-reduced media are required for their isolation. Two general strategies are employed: 1) Enrichment techniques are generally very successful because few other microorganisms are capable of utilizing the major methanogenic substrates under anaerobic conditions. In addition, the sulfate- and sulfur-reducing bacteria, the denitrifying bacteria, and the photosynthetic bacteria may be further excluded by omitting sulfate, sulfur, and nitrate from the enrichment medium and performing the incubations in the dark. While the chemolithotrophic acetogenic bacteria may also be enriched under these conditions, they may be eliminated in subsequent steps. 2) Antibiotics can be employed as selective inhibi-

tors of the eubacteria. Since the methanogens are archaeobacteria, many of their enzyme systems are unaffected by a wide variety of common antibiotics.

Enrichments are performed in media that simulate the source of the sample and mimic the environmental pH, salt concentration, and temperature. The presence of methanogens in the enrichment is determined by gas chromatographic analysis of the headspace for methane. Consumption of $H_2 + CO_2$ or gas production from acetate or methylamines is a less reliable indicator of methanogenic activity. For example, acetogenic bacteria will also consume $H_2 + CO_2$ gas under the same conditions as the methanogens (see Chapter 21). Likewise, in enrichments containing sediments or large amounts of other organic material, gas may be produced by fermentative bacteria. If the samples are believed to contain high numbers of methanogens, they are first serially diluted in medium, and after incubation, the highest dilution with methanogenic activity is processed further. Mineral medium is used to obtain autotrophic methanogens. Although most of the heterotrophic contaminants will be eliminated upon successive transfers, low levels of some contaminants may persist due to growth on exudates of the methanogen or on lysed cells. Because many methanogens have nutritional requirements for low levels of acetate, amino acids, volatile fatty acids, or vitamins, a complex enrichment medium is often more suitable. For very fastidious methanogens, the enrichment medium may also be amended with 30% rumen fluid or sludge extract (Mah and Smith, 1981). In this case, the heterotrophic contaminants must be eliminated by colony isolation on solid medium. Antibiotics may also reduce the numbers of contaminants. However, because of the rapid selection of antibiotic resistant contaminants, they are seldom sufficient alone for the isolation of pure cultures.

Antibiotics are especially useful when used in conjunction with enrichment techniques. Because some antibiotics are toxic to certain methanogens (Böck and Kandler, 1985), it is also useful to test their effects on the enrichment culture. Success has been obtained with a variety of antibiotics, used either singly or in combination (Table 3). However, to avoid the selection of resistant contaminants, the antibiotics are only utilized for one or two transfers. In addition, the antibiotics must be omitted from the medium when determining the purity of the isolated methanogen.

When a successful enrichment has been obtained, the methanogen may be observed by fluorescence microscopy (Doddema and Vogels, 1978). For optimal fluorescence, the excitation

wavelength should be between 350 and 420 nm. Under these conditions, most species autofluoresce a blue-green color due to an abundance of coenzyme F₄₂₀. However, the intensity of the fluorescence varies greatly, and it may not be observed following growth of *Methanosaeta* on acetate (Zehnder et al., 1980). The fluorescence may also rapidly fade within a few seconds or be absent in older and inactive cells. In spite of these limitations, fluorescence microscopy is useful for determining if more than one type of methanogen is present in an enrichment or for checking the relative purity of the culture.

The isolation of single colonies on solid medium is usually necessary for obtaining axenic cultures of methanogens. Solid medium is prepared by the roll-tube technique or in petri plates in an anaerobic glove box. One advantage of roll tubes is that colonies of methanogens may be frequently visualized through the wall of the tube by their fluorescence. In any case, the anaerobic techniques must be stringent enough to ensure that the plating efficiency is high, since, otherwise, most of the colonies may contain contaminants that are less oxygen-sensitive than the methanogen. In a minimal medium, it may not be possible to obtain isolated colonies because

the methanogen may require a nutrient produced by a contaminating organism. For instance, in media lacking acetate, this nutrient may be produced by the fermentation of amino acids by a contaminating bacterium. Under such conditions, if acetate is required for growth of the methanogen, colonies will contain a mixture of both organisms.

In addition to the normal microbiological tests for axenic cultures, certain growth tests are useful to establish culture purity. Growth should not be observed in complex medium prepared without the substrates for methanogenesis. The medium is prepared with the same salt and trace nutrient composition as the enrichment medium, but 0.2–0.4% trypticase peptones or casamino acids and 0.2% glucose are added. Yeast extract, a source of B-vitamins, frequently contains small amounts of formate and acetate and should be avoided. Growth in a complex medium without a methanogenic substrate indicates the presence of a heterotrophic contaminant. The plating efficiency of the methanogenic culture in the enrichment medium should also be greater than 50%. If it is much lower, it is possible that growth is dependent upon crossfeeding between the methanogen and another organism.

Techniques for Culturing Methanogenic Bacteria

The methodology for culturing methanogenic bacteria is based upon the pioneering work of Hungate on anaerobic rumen bacteria (1969). Anaerobiosis is achieved by the replacement of air with oxygen-free gases and the addition of a reducing agent. The culture vessels are made of glass and sealed with butyl rubber stoppers. Oxygen-permeable rubber and plastic are avoided whenever possible. Media are dispensed in an anaerobic glove box, under a stream of oxygen-free gas, or with a glass syringe. Commercial gases are scrubbed to remove traces of contaminating oxygen. Details of the procedures are described in the primary literature (Balch and Wolfe, 1976; Macy et al., 1972) and in several recent reviews (Ljungdahl and Wiegel, 1986; Mah and Smith, 1981).

Enrichment Media for Growth of Methanogens

A large number of different types of media have been formulated for the growth of methanogens. Many are described in the original species descriptions cited elsewhere in this chapter. Therefore, only a few general media will be described. Although most methanogens will grow in one of these media, optimal growth may require modification of the concentrations of some of the components or special additions.

Medium 1 for Freshwater, Sewage, and Intestinal Species

Its composition is similar to media described earlier (Balch et al., 1979; Mah and Smith, 1981). Its composition is (per liter of medium):

Yeast extract	2.0 g
Trypticase peptones	2.0 g
Salt solution A (see below)	10 ml
Phosphate solution (200 g/l of $K_2HPO_4 \cdot 3H_2O$)	2 ml
Resazurin solution (0.5 g/l in water)	2 ml
Sodium acetate solution (136 g/l of Na acetate $\cdot 3H_2O$)	10 ml
Trace element solution (see below)	10 ml
Vitamin solution (see below)	10 ml
$NaHCO_3$	5.0 g
Cysteine/hydrochloride	0.5 g
Sulfide solution (see below)	20 ml

Salt solution A is composed of (per liter):

NH_4Cl	100 g
$MgCl_2 \cdot 6H_2O$	100 g
$CaCl_2 \cdot 2H_2O$	40 g

After dissolving the salts, the pH is adjusted to 4 with HCl.

The trace element solution is modified from Wolin et al. 1963 and is composed of (per liter):

Nitrilotriacetic acid	1.5 g
$Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$	0.2 g
Na_2SeO_3	0.2 g
$CoCl_2 \cdot 6H_2O$	0.1 g
$MnSO_4 \cdot 2H_2O$	0.1 g
$Na_2MoO_4 \cdot 2H_2O$	0.1 g
$Na_2WO_4 \cdot 2H_2O$	0.1 g
$ZnSO_4 \cdot 7H_2O$	0.1 g
$AlCl_3 \cdot 6H_2O$	0.04 g
$NiCl_2 \cdot 6H_2O$	0.025 g
H_3BO_3	0.01 g
$CuSO_4 \cdot 5H_2O$	0.01 g

To prepare the trace element solution, dissolve the nitrilotriacetic acid in 800 ml of water and adjust the pH to 6.5 with KOH. Then dissolve the minerals in order, adjust the pH to 7.0, and bring the volume to 1 liter.

The vitamin solution is modified from Bryant et al. 1971 and is composed of (per liter):

<i>p</i> -Aminobenzoic acid	10 mg
Nicotinic acid	10 mg
Calcium pantothenate	10 mg
Pyridoxine hydrochloride	10 mg
Riboflavin	10 mg
Thiamine hydrochloride	10 mg
Biotin	5 mg
Folic acid	5 mg
α -Lipoic acid	5 mg
Vitamin B ₁₂ (stored in dark at 5°C)	5 mg

The sodium sulfide solution is prepared in anoxic water under N_2 gas. A 10 mM solution of NaOH, 110 ml, is boiled under a stream of N_2 gas until the volume is reduced to 100 ml. It is then allowed to cool under a stream of N_2 gas in a fume hood. Because sodium sulfide is very toxic, precautions must be taken to avoid contact with the solid and the solution, as well as inhalation of the vapor. To remove sulfur oxides from the surface, a large crystal of Na_2S9H_2O (about 3 g) is washed in 50 ml of water for a few seconds. The crystal is blotted dry on a paper towel and weighed. About 2.5 g should remain and is immediately added to the anaerobic solution of NaOH. The sulfide solution is then dispensed anaerobically into tubes or bottles, pressurized with 100 kPa of N_2 , and autoclaved. If an anaerobic glove box is available, the tubes or bottles and their stoppers should be placed in the glove box 24 hours before use to remove adsorbed O_2 . The stoppers must fit tightly and should not be greased. They may be lubricated with anaerobic water to facilitate insertion and twisting into place. After autoclaving, the sulfide solution may be stored for up to two weeks or until the solution becomes cloudy. For organisms like *Methanococcus*, best results are obtained if the sulfide solution is stored in the anaerobic chamber immediately after autoclaving.

Medium 2 for Methanogens Isolated from Marine Environments

It is modified from Romesser et al. 1979, and it is composed of (per liter):

Salt solution B (see below)	500 ml
Phosphate solution (14 g/l of $K_2HPO_4 \cdot 3H_2O$)	10 ml
Trace element solution	10 ml

Vitamin solution	10 ml
Iron stock solution (see below)	5 ml
Sodium acetate solution (136 g/l of sodium acetate · 3H ₂ O)	10 ml
Resazurin solution (0.5 g/l in water)	2 ml
NaCl solution (293 g/l)	75 ml
Yeast extract	2 g
NaHCO ₃	5 g
Cysteine hydrochloride	0.5 g
Sulfide solution	20 ml

Salt solution B is composed of (per liter):

CaCl ₂ · 2H ₂ O	0.28 g
KCl	0.67 g
NH ₄ Cl	1.00 g
MgCl ₂ · 6H ₂ O	5.50 g
MgSO ₄ · 7H ₂ O	6.90 g

To prepare the iron stock solution, add 0.2 g of Fe(NH₄)₂(SO₄)₂ · 6H₂O to a screw-top bottle. Then add 0.1 ml of concentrated HCl followed by 100 ml of H₂O. The solution should be replaced every four weeks.

Medium 3 for Moderately Halophilic Methanogens

It contains the same components as Medium 1 except that 88 g/l of NaCl is added.

As described above, the media do not contain a substrate for methanogenesis. For growth on H₂ + CO₂ (80 : 20 vol/vol), the gas mixture is added after dispensing and sterilizing the medium, and the culture tubes are pressurized to 100 kPa above atmospheric pressure. After inoculation, the culture tubes are pressurized to 240 kPa. For growth on other substrates, the gas atmosphere is 100 kPa of N₂ + CO₂ (80:20 vol/vol), and the NaHCO₃ concentration is reduced to 2 g/l. For growth on acetate, 50 ml of the sodium acetate solution (1 M) is added. For growth on trimethylamine/hydrochloride, 12 ml of a 1 M solution (95.5 g/l) is added. For growth on methanol, 4 ml of methanol is added per liter. For growth on 2-propanol, 1-propanol, ethanol, 2-butanol, and 1-butanol, the alcohols are added at a final concentration of 20–30 mM (Widdel, 1986). For growth on formate, 4 g/l of sodium formate is added. To control the pH in batch cultures, a formic-acid reservoir may also be added to the culture tube (Schauer and Whitman, 1989). Regardless of the substrate, care must be taken to avoid exceeding the pressure limit of the culture vessels. For instance, 10 ml of medium containing 50 mM acetate will generate nearly 15 ml of gas if the acetate is completely converted to CO₂ and CH₄. Therefore, the headspace of the culture vessel must be large enough to prevent an excessive increase in pressure, which could lead to an explosion. To minimize this danger, the culture vessels should be handled in wire baskets or metal cans. During growth on H₂ + CO₂, the opposite problem occurs. Because the methanogens consume 5 moles of gas for every

mole of CH₄ produced, the vessel will quickly develop a negative pressure. Also, as the partial pressure of CO₂ decreases, the medium will become strongly alkaline, which may inhibit growth and cause cell lysis. To minimize these problems, the volume of the headspace should be at least five times the volume of the medium, and the culture vessel should be pressurized periodically throughout the growth period. For better control of the pH, the headspace may also be repressurized with H₂ + CO₂ (75 : 25 vol/vol) to fully replenish the CO₂ consumed. For the thermophilic species, attention must also be given to the expansion of gas at higher temperatures.

All three media may be prepared by the same method. All the components are combined except the gaseous substrates and the reducing agents, cysteine hydrochloride and the sulfide solution. The medium is then brought to a boil under a stream of N₂ + CO₂ gas (80 : 20 vol/vol) and immediately removed from the heat. Solid cysteine hydrochloride is added, and the medium is allowed to cool under a stream of N₂ + CO₂. During this time, the oxygen indicator resazurin changes from blue to pink to colorless. The change from blue to pink occurs upon the pH-dependent formation of resorufin. The change from pink to clear occurs upon the reduction of resorufin to dihydroresorufin. When the medium has cooled to about 50°C, it can be dispensed anaerobically to the culture tubes or bottles under a stream of O₂-free N₂ + CO₂ gas or in an anaerobic glove box (Ljungdahl and Wiegel, 1986; Mah and Smith, 1981). For growth on H₂ + CO₂, the gas atmosphere of the culture tubes is exchanged before autoclaving. After autoclaving, the pH of the bicarbonate-CO₂ buffered medium is 6.8–7.0.

The media may be stored for several months in the anaerobic glove box or for about one week on the laboratory bench prior to the addition of the sulfide solution. One hour before inoculation, one part of the sterile sulfide solution is added anaerobically to 50 parts of sterile medium. Some species appear to be especially sensitive to the products of sulfide oxidation. When small inocula are used, more reproducible results are obtained by adding the sulfide solution 24 hours before the inoculation.

For growth of fastidious methanogens, the media may be amended (per liter) with 100–300 ml of clarified rumen fluid, 10 ml of a volatile fatty acid mixture, or 2 ml of boiled cell extract (BCE) of a methanogen (Mah and Smith, 1981; Tanner and Wolfe, 1988). To prepare rumen fluid, samples of the rumen contents are obtained from a fistulated animal, a mouth tube, or a slaughtered animal. The fluid is separated from the large solids by filtration through 8 layers of cheese cloth into an Erlenmeyer flask. The fluid

is then centrifuged under anoxic conditions at $10,000 \times g$ for 20 minutes to remove microbial cells and small particulate matter. The supernatant is decanted and sparged slowly with CO_2 overnight. Then it is dispensed into serum bottles, flushed with CO_2 , and autoclaved. The volatile fatty acid mixture is modified from Bryant et al. 1971 and is composed as follows: 46 ml of butyric, 46 ml of isobutyric, 55 ml of isovaleric, 55 ml of DL-2-methylbutyric, 37 ml of propionic, and 54 ml of valeric acids are added to 500 ml of water in a fume hood, neutralized (by litmus) with 2 M NaOH, and brought to a final volume of 1 liter.

Some methanogens require growth factors that are only produced by other methanogenic bacteria. These factors may be obtained from rumen fluid or BCE (Tanner and Wolfe, 1988). To prepare BCE, 10 g wet weight of methanogen cells are resuspended in 20 ml of anaerobic 20 mM potassium phosphate buffer, pH 7.0, and incubated under a stream of N_2 gas in a boiling water bath for one hour. After cooling, the suspension is centrifuged anaerobically at $20,000 \times g$ for 30 min at 4°C . The resulting supernatant, BCE, is stored anaerobically at -20°C .

Mineral media may be prepared by omitting the organic supplements: yeast extract, trypticase, acetate, and cysteine. However, cysteine also functions as a reducing agent. Therefore, the medium will remain oxidized until the sulfide solution is added. In this case, the sulfide solution should be added 24 h before inoculation.

For growth of the alkalophilic methanogens, the medium is prepared under a N_2 atmosphere. The NaHCO_3 concentration is increased to 10 g/l (pH 8.5) or replaced with 3 g/l of NaHCO_3 plus 2 g/l of Na_2CO_3 (pH 9.3; Mathrani et al., 1988; Worakit et al., 1986). If H_2 is the substrate, the culture is initially pressurized with 50 kPa H_2 . CO_2 is not added initially to avoid acidification of the medium. The gas is then replenished with $\text{H}_2 + \text{CO}_2$ (75:25 vol/vol) during growth, stoichiometrically replacing the CO_2 reduced to methane. For mass culture, gas additions are controlled by a pH auxostat (Boone et al., 1987).

Solid medium is prepared by the addition of agar or Gelrite during the medium preparation. For roll tubes or bottles, the medium plus sulfide with 2% agar or 1% Gelrite is allowed to coat the walls to provide a surface for inoculation (Harris, 1985; Hermann et al., 1986; Hungate, 1969). The agar surface may be streaked or the cells may be added as a soft agar overlay. Alternatively, molten agar may be cooled to 45°C and inoculated prior to solidification. Petri plates containing 0.8–2% agar or Gelrite (Kelco Div., Merck & Co., Inc., San Diego, Calif.) may be prepared in an anaerobic glove box (Balch et al., 1979). In this case, the plates are prepared with-

out sulfide (Jones et al., 1983c). After inoculation, the plates are pressurized with $\text{H}_2 + \text{CO}_2$ or $\text{N}_2 + \text{CO}_2$ in a cannister and removed from the chamber. An open tube containing 0.75 ml of 20% $\text{Na}_2\text{S} \cdot 9\text{H}_2\text{O}$ per liter of cannister volume is added just prior to pressurization. Because the CO_2 neutralizes the sulfide solution, volatile H_2S (about 1.5%) is generated inside the cannister. Because H_2S is toxic, the cannister must either be opened in a fume hood or be flushed with $\text{N}_2 + \text{CO}_2$ gas before opening in the anaerobic glove box.

Measurement of Growth

In many cases, the growth of methanogens can be measured by normal microbiological techniques. However, some organisms grow as aggregates or have very low cell yields, and it is difficult to measure growth turbidimetrically or by other common techniques. An alternative is to measure CH_4 accumulation in the headspace by gas chromatography. However, whenever product formation is used to estimate growth rate, it is important to insure that cell growth is balanced, that is, product formation is proportional to the increase in cell mass. Thus, control experiments should demonstrate a correlation between CH_4 formation and cell mass. This method is additionally complicated because upon inoculation, only cells and not the initial product are transferred (Powell, 1983). Therefore, plots of the logarithm of CH_4 accumulated versus time are nonlinear for about four generations, and the growth curves appear to be convex. This artifact results in an overestimate of the specific growth rate. To correct for this effect, the logarithm of the rate of methane formation versus time should be plotted (Powell, 1983). This replot is linear, and the specific growth rate is equal to the slope.

Maintenance of Stock Cultures

Many of the same techniques used for storage of stock cultures of other anaerobes are suitable for at least some of the methanogens (Hippe, 1984). While freezing in liquid nitrogen is a very reliable method, less-expensive alternatives may be employed for laboratory collections. Lyophilization in horse serum plus 7.5% glucose and 3 mg/ml of ferrous sulfide followed by storage at either 8° or -70°C is suitable for many species of *Methanobacteriaceae* and *Methanosarcina* (Hippe, 1984). However, this method is less effective for *Methanococcus* and *Methanospirillum*. Many methanogens can also be stored on agar slants at 4°C for one year if oxygen is excluded (Winter, 1983). Likewise, storage at -18°C in medium containing 50% glycerol in sealed glass ampules

is effective for 20 months. *Methanococcus* cultures can be preserved in medium containing 25% glycerol in screw-top vials at -70°C for 30 months without special anaerobic precautions (Whitman et al., 1986). *Methanobrevibacter* species and some other methanogens can be stored in biphasic cultures at -76°C for 6–12 months (Miller, 1989). Culture tubes are prepared with a slant of double-strength medium containing 3% agar and twice the usual concentration of reducing agents. One-third volume of reduced, single-strength broth is added. The tube is inoculated and allowed to grow to a heavy density. The culture is then cooled for 1 hour at 4°C prior to freezing at -76°C .

Cultures of the type strains of most species of methanogens are available through the Deutsche Sammlung von Mikroorganismen (Braunschweig, FRG) and the OGC Collection of Methanogenic Archaeobacteria (Oregon Graduate Institute, Beaverton, Oregon, USA).

Identification

Three major difficulties are encountered in the identification of isolates of methanogenic bacteria: 1) Most of the species descriptions are based upon the examination of only a few strains. Therefore, it is frequently not known if the phenotypic characterization is representative of the species. 2) Probably only a fraction of the methanogens in nature have been described. Therefore, a new isolate may represent an undescribed species or subspecies. 3) Because of their restricted catabolism coupled with extreme genetic diversity, phenotypic characters alone are often insufficient to identify methanogens. For these reasons, phylogenetic methods such as DNA-DNA hybridization and ribosomal RNA sequence analysis are frequently necessary for a definitive assignment (Boone and Whitman, 1988). Other techniques that have proven useful in the identification of methanogens include analysis of their antigenic relationships, polyamine content, molecular weights of the methylreductase subunits, and molecular weights of the polar lipids. Cross-reactivity of specific immunoglobulins has proven useful for identifying methanogens at the species and genus level (Conway de Macario et al., 1981). For distinguishing among members of different families, data on the relative distribution of putrescine, spermidine, spermine, and homospermidine, as well as the molecular weight of the small subunit of component C of the methylreductase, are useful (Kneifel et al., 1986; Rouvière and Wolfe, 1987). Likewise, the distribution of polar lipids distinguishes the families of methanogens (Koga et al., 1987; Morii et al., 1988).

Fig. 1. Phylogenetic tree for the methanogenic bacteria and other archaeobacteria based upon 16S rRNA sequences. *Mc.* *Methanococcus*; *Mt.*, *Methanothermus*; *M.*, *Methanobacterium*; *Mbb.*, *Methanobrevibacter*; *Ms.*, *Methanospirillum*; *Mp.*, *Methanoplanus*; *Msa.*, *Methanosarcina*; *Msa.*, *Methanosaeta*; *H.*, *Halobacterium*; *T.*, *Thermoplasma*; *A.*, *Archaeoglobus*; *Tc.*, *Thermococcus*; *Tp.*, *Thermoproteus*; *Tf.*, *Thermofilum*; *P.*, *Pyrodictium*; *S.*, *Sulfolobus*; and *D.*, *Desulfurococcus*. (P. E. Rouvière and C. R. Woese, personal communication.)

Nineteen genera and more than 50 species of methanogenic bacteria have been described. The current taxonomy reflects the phylogeny described by the oligonucleotide catalogs of the 16S rRNAs (Balch et al., 1979). More recent information, which includes nearly complete sequences of the 16S rRNA and many new species, has confirmed many of these earlier conclusions. The current phylogenetic tree supports the classification of the methanogens into three major groups that correspond to the orders proposed by Balch et al., 1979 (Fig. 1). The orders have been further divided into six families, and the creation of additional families may be warranted to include other deep branches of the major lineages. However, the proposal to place *Methanoplanus* in a separate family (Wildgruber et al., 1982) is not supported by the most recent information.

At present, three orders and six families are recognized within the methanogens (Tables 4 and 5). As indicated in the footnotes to Table 4, most genera have not been formally assigned to an order and family. While the present scheme is consistent with the current phylogenetic and phenotypic data, future changes are to be expected.

Two families, the Methanobacteriaceae and the Methanothermaceae, are closely related. These methanogens possess cell walls composed in part of pseudomurein (Kandler and König, 1985). The cell walls of the Methanothermaceae also contain an additional surface layer composed of protein. The family Methanothermaceae contains one genus, *Methanothermus*,

Table 4. Major taxonomic groups of methanogenic bacteria.

Order	Family	Genus
Methanobacteriales	Methanobacteriaceae (type) ^a	<i>Methanobacterium</i> (type) ^a

^aType family of the order or type genus of the family.^bNot formally placed within the family.^cWhile not formally placed within the family, it includes species originally placed within a genus of the family.

Table 5. Some characteristics of the methanogen families.

Family	Characteristics
Methanobacteriaceae ^a	Long or short rods, which use H ₂ + CO ₂ and sometimes formate or alcohols as substrates for methanogenesis; cocci, which utilize only H ₂ + methanol; mostly Gram-positive; contain pseudomurein; nonmotile; GC content, 23–61 mol%.
Methanothermaceae	Rods; substrate for methanogenesis is H ₂ + CO ₂ ; Gram-positive; contain pseudomurein; nonmotile; extreme thermophiles; GC content, 33–34 mol%.
Methanococcaceae	Irregular cocci; substrates for methanogenesis are H ₂ + CO ₂ and formate; Gram-negative; motile; GC content, 29–34 mol%.
Methanomicrobiaceae	Rods, spirals, plates, or irregular cocci; substrates for methanogenesis are H ₂ + CO ₂ , frequently formate, and sometimes alcohols; Gram-negative; motile or nonmotile; GC content, 39–61 mol%.
Methanocorpusculaceae	Small, irregular cocci; substrates for methanogenesis are H ₂ + CO ₂ , formate, and sometimes alcohols; Gram-negative; motile or nonmotile; GC content, 48–52 mol%.
Methanosarcinaceae	Pseudosarcina, irregular cocci, sheathed rods; substrates for methanogenesis are sometimes H ₂ + CO ₂ , acetate, and methyl compounds; formate is never used; Gram-positive or negative; frequently nonmotile; GC content, 36–52 mol%.

^aIncluding *Methanosphaera*.

both species of which are extremely thermophilic bacilli with temperature optima of 83–88°C. Like in many of the Methanobacteriaceae, the only substrate for methanogenesis is H₂ + CO₂. The family Methanobacteriaceae contains two genera, composed of thermophilic as well as mesophilic species. These genera, *Methanobacterium* and *Methanobrevibacter*, are bacilli that utilize either H₂ + CO₂ alone or H₂ + CO₂ and formate as substrates for methanogenesis. An additional genus, *Methanosphaera*, is closely related to the *Methanobacteriaceae*, although it has not yet been formally placed within this family. It includes two coccoid species that utilize H₂ + methanol as substrates. These organisms are unique in that they are incapable of

both the reduction of CO₂ to methane and the oxidation of methanol to CO₂ (Miller and Wolin, 1983).

The family Methanococcaceae contains one genus of irregular cocci, *Methanococcus*, most species of which utilize both H₂ + CO₂ and formate as substrates. The six known species of *Methanococcus* contain protein cell walls and are either mesophilic or extremely thermophilic. Most species are also autotrophic. By the criterion of the 16S rRNA sequences, this genus is very diverse (Fig. 1). To maintain genera of equal phylogenetic depth, the two thermophilic species should be placed in two new genera.

The family Methanosarcinaceae contains all the methanogens capable of utilizing acetate as

a substrate for methanogenesis or oxidizing the methyl groups of C-1 compounds. Formate is not utilized by any species in this family and most species are also unable to grow on $H_2 + CO_2$. Seven genera have been described. The genus *Methanosarcina* contains six species of cocci, which may occur singly, in packets, or in large pseudoparenchyma (Zhilina, 1976). The aggregates are held together by methanochondroitin, a polymer of N-acetyl-D-galactosamine and D-glucuronic acid similar to animal chondroitin (Kreisl and Kandler, 1986). Pseudomurein is absent. Pseudoparenchyma formation is species and strain specific and varies even in strains that do form aggregates, depending upon the culture conditions and growth stage. Therefore, the absence of aggregation is not sufficient evidence to exclude an isolate from this genus. Another typical property of this genus is the ability to utilize both acetate and C-1 compounds as substrates for methanogenesis. In addition, some species also utilize $H_2 + CO_2$. Other genera in this family that contain cocci are distinctive in their ability to utilize only C-1 compounds as substrates for methanogenesis. These genera include *Methanobrevibacter*, *Methanococcus*, *Methanohalobium*, *Halomethanococcus*, and *Methanohalophilus*. The last three genera contain the moderately and extremely halophilic species of methanogens, but have not been formally placed within this family. An additional species, *Methanococcus halophilus*, should probably also be classified with these organisms on the basis of its 5S rRNA sequence (Lysenko and Zhilina, 1985). The last genus, *Methanosaeta* ("Methanothrix"), includes large sheathed rods that can only utilize acetate as a substrate for methanogenesis.

The family Methanomicrobiaceae contains six genera of different morphological types with

similar physiology. With one exception, all species utilize both $H_2 + CO_2$ and formate as substrates. Two genera, *Methanogenium* and *Methanoculleus*, are cocci that can be distinguished from the methanococci by their slower growth rates under optimal conditions, more complex nutritional requirements, higher GC content, and lower NaCl requirements. The genus *Methanospirillum* has a distinctive spiral morphology, and the genus *Methanoplanus* contains plate-like or irregular disk-shaped species. Lastly, the genera *Methanomicrobium* and *Methanolacinia* contain rod-shaped species. These species may be distinguished from *Methanobrevibacter* because they stain Gram-negative due to the absence of pseudomurein and they have a higher GC content.

The family Methanocorpusculaceae is related to the family Methanomicrobiaceae. It contains one genus, *Methanocorpusculum*, of very small cocci. The complex nutritional requirements of the species of this family distinguishes them from species of *Methanococcus*. The absence of a requirement for NaCl for good growth distinguishes them from species of *Methanogenium* and *Methanoculleus*.

Characteristics of Methanogenic Bacteria

Some of the most important and most distinctive features of methanogenic species will be described in this section. More detailed descriptions of the various taxa of bacteria may be found in the original citations, which are included in the footnotes to Tables 6 to 16. Whenever possible, the descriptions summarize the properties of all the described strains as well

Table 6. Some characteristic properties of species of the genus.

Species	Cell width (μm)	Cell length (μm)	Temperature optimum (°C)	pH optimum	Required organic growth factors ^a	GC content (mol%)

as the type strain. Because many of the growth descriptions depend greatly upon the experimental conditions, some caution must be exercised in the evaluation of results from different laboratories. In particular, variation in the growth optima may occur depending on whether growth is measured by turbidity, methane formation, growth rate, or growth yield.

The Family Methanobacteriaceae

The presence of a peptidoglycan chemically different from murein (called pseudomurein) is

ubiquitous among species of the family Methanobacteriaceae. This peptidoglycan, like its counterpart in eubacteria, confers shape to these rods and coccobacilli, which have a wall structure typical of Gram-positive bacteria (Kandler and König, 1985). While the cells frequently stain Gram-positive, they are not formally considered Gram-positive because the cell wall is not composed of true murein. Many of the rod-shaped methanogens are in this family, and the morphologies of representative species are shown in Fig. 2. The exceptions are a few other species that have protein cell walls and are sensitive to

lysis by detergents (*Methanomicrobium*) or are enclosed within a sheath that appears to confer the shape (*Methanosaeta*). The family Methanobacteriaceae contains three genera.

METHANOBACTERIUM. The species of *Methanobacterium* vary widely in length, and filaments are common (Table 6). One species, *M. thermoaggregans*, forms large multicellular aggregates. The rod-shaped cells are often irregularly crooked. All species grow with H₂ + CO₂ as a

substrate for methanogenesis. In addition, formate is used by *M. formicicum*, "*M. palustre*," and *M. thermoformicicum*. The secondary alcohols 2-propanol and 2-butanol are also utilized by *M. bryantii*, *M. formicicum*, and "*M. palustre*" (Widdel et al., 1988; Zellner and Winter, 1987a). In addition, 2-propanol and 2-butanol support low levels of methane synthesis but not growth of the moderately acidophilic species *M. espanolae* (Patel et al., 1990). Most species of *Methanobacterium* are capable of autotrophic growth

Fig. 2. Phase contrast photomicrographs of some rod-shaped methanogenic bacteria of the genera *Methanobrevibacter*, *Methanobacterium*, and *Methanomicrobium*. (A) *Methanobrevibacter ruminantium*; (B) *Methanomicrobium mobile* (stained preparation); (C) *Methanobacterium formicicum*; (D) *Methanobacterium bryantii*; (E) *Methanobrevibacter arboriphilicus*; (F) *Methanobacterium thermoautotrophicum*. (From Mah and Smith, 1981.)

with CO₂ as a sole carbon source. However, acetate, cysteine, and yeast extract are frequently stimulatory. *M. bryantii* is also stimulated by a mixture of B-vitamins. The alkaliphilic species, *M. alcaliphilum* and *M. thermoalcaliphilum*, both require yeast extract for growth, and their major carbon sources are not known.

While the nitrogen and sulfur sources have not been investigated systematically, all species of *Methanobacterium* that have been tested use ammonium, sulfide, and elemental sulfur. In addition, *M. ivanovii* uses glutamine as a sole nitrogen source (Bhatnagar et al., 1984) and *M. thermoautotrophicum* uses glutamine and urea. Note that at the high temperature at which the thermophile is grown glutamine decomposes rapidly in the medium (Friedmann and Thauer, 1987). *M. ivanovii*, *M. bryantii*, and *M. thermoautotrophicum* use cysteine as a sole sulfur source and *M. ivanovii* also uses methionine. *M. thermoautotrophicum* also uses sulfite and thiosulfate as sole sulfur sources (Daniels et al., 1986).

The species of *Methanobacterium* have been isolated from anaerobic digestors, sewage sludge, manure, groundwater, and formation water of oil-bearing rocks. In general, these habitats contain low NaCl concentrations, which are optimal for growth. Concentrations above 0.2 M are frequently inhibitory. *M. wolfei* also has a growth requirement for 8 μM tungstate, which is an unusually high concentration.

METHANOBREVIABACTER. Species of the genus *Methanobrevibacter* are oblong cocci or very short rods (Table 7). Flagella or fimbriae are not observed. All species utilize H₂ + CO₂ as substrates for methanogenesis. Formate is utilized by some species. Secondary alcohols were not utilized by the species tested, *M. arboriphilicus* and *M. smithii* (Widdel et al., 1988; Zellner and Winter, 1987a). The optimum pH for growth is near 7, except for *M. arboriphilicus*, which has an optimum near 8.0. *M. ruminantium* was isolated from the rumen and has very complex nutritional requirements. These requirements may be met by rumen fluid, acetate, 2-methylbutyrate, coenzyme M, or a mixture of amino acids. In addition, several similar strains have been isolated from the rumen that do not require coenzyme M (Lovley et al., 1984; Miller et al., 1986). At present, it is not known whether these strains represent new species or atypical strains of *M. ruminantium*. *M. smithii* appears to be a common methanogen in the human gastrointestinal tract (Miller and Wolin, 1982; Weaver et al., 1986). Acetate, trypticase, yeast extract, and B-vitamins are required or stimulatory for growth. In contrast to *M. ruminantium* and *M. arboriphilicus*, growth of *M. smithii* is not inhibited by bile salts.

Methanobrevibacter species have also been isolated from the feces of the horse, pig, goose, and rat (Miller and Wolin, 1986). The strain from the rat may be a new and undescribed species. On the basis of serological evidence, it has also been proposed that an additional species of *Methanobrevibacter* may predominate in some human feces (Misawa et al., 1986).

METHANOSPHAERA. *Methanospaera* is distinct from other Methanobacteriaceae because it is coccoid and cannot reduce CO₂ to CH₄. Cells are capable of growth only by using H₂ to reduce methanol. However, the cell walls contain pseudomurein, and sequence analysis of the 16S rRNA suggests that it is closely related to the Methanobacteriaceae. Cells are spherical and occur singly or in pairs, tetrads, or small clusters (Table 8). So far, they are found only in the mammalian colon, and they are resistant to bile salts. Cells are chemoorganotrophic, and they require CO₂, acetate, some vitamins, and amino acids for growth. In addition to the amino acids, *M. stadtmaniae* requires NH₃ as a nitrogen source. Although the two species are very similar phenotypically, they can be easily distinguished by DNA-DNA hybridization or serology.

The Family Methanothermaceae

This family contains one genus, *Methanothermus*, which is extremely thermophilic and rod-shaped (Table 9). The temperature optimum is between 80° and 90°C and no growth occurs below 60°C or above 97°C. Its habitat is geothermal (85° to 101°C) waters and muds in Iceland, and it has not been found in similar habitats in other geographical locations. H₂ + CO₂ is the only substrate for methanogenesis. Colonies do not grow on agar plates; therefore, polysilicate plates have been used. Unlike those of the Methanobacteriaceae, the cell wall of *Methanothermus* has an S-layer external to the pseudomurein layer. Two species of *Methanothermus* have been described: *M. fervidus* grows as dispersed cells and never forms filaments whereas *M. sociabilis* forms aggregates as large as 3 mm in diameter and contains pili-like appendages. These species also differ in their lipid and pseudomurein composition (Lauerer et al., 1986). Growth of each species is inhibited in vessels made of borosilicate glass, so soda-lime glass vessels are used.

The Family Methanococcaceae

Methanococcaceae contains one genus, *Methanococcus*, which is composed of six species of mesophilic and thermophilic organisms (Table 10). An additional species has been proposed, *M. deltae*, but it is probably a subspecies of *M. mari-*

Fig. 3. Phase contrast photomicrograph of *Methanococcus voltae*. (From Mah and Smith, 1981.)

paludis (Corder et al., 1983; Whitman, 1989). The methanococci are all irregular cocci, 1–2 μm in diameter (Fig. 3). Thus, they are not easily distinguished morphologically from each other or other coccal methanogens. The cell wall is composed of an S-layer containing hexagonally arranged protein subunits (Koval and Jarrell, 1987; Nusser and König, 1987). The molecular weights of all the major wall proteins are less than 90,000, which distinguishes them from the S-layer proteins of the members of the family Methanomicrobiaceae. In addition, the S-layer proteins of the methanococci are not glycosylated. Cells lyse rapidly in 0.01% sodium dodecyl sulfate and in distilled water and they disintegrate upon heat fixation to microscope slides. The methanococci are motile, with one or two polar tufts of flagella. Isolated flagella of *M. voltae* are composed of two flagellins with molecular weights of 31,000 and 33,000 (Kalmokoff et al., 1988). The basal body is knob-like and lacks the complex ultrastructure typical of the eubacterial basal body.

The methanococci utilize $\text{H}_2 + \text{CO}_2$ as a substrate for methanogenesis. Formate is also an electron donor for all the methanococci except for two of the three described strains of *M. jannaschii*. None of the methanococci utilize acetate, methyl compounds, or alcohols as substrates for methanogenesis. Except for *M. voltae*, the methanococci are capable of rapid autotrophic growth with CO_2 as the sole carbon source. *M. voltae* requires acetate, isoleucine (or propionate or 2-methylbutyrate), and leucine (or isovalerate) as carbon sources (for a review see Jarrell and Koval, 1989). *M. voltae* grows mixotrophically, and its cellular carbon is derived from both the assimilation of exogenous acetate and autotrophic acetyl-CoA biosynthesis (Shieh et al., 1988). *M. maripaludis* also assimilates ace-

tate, glycine, and a variety of nonpolar and basic amino acids (Whitman et al., 1987). In contrast, *M. vannieli* and "*M. aeolicus*" do not assimilate amino acids when they are provided at low concentrations, and acetate is not stimulatory to growth. Pantoyl lactone stimulates the growth of *M. voltae*, but water-soluble vitamins do not affect the growth rates of the other mesophilic methanococci.

The methanococci utilize ammonia as a sole nitrogen source. *M. maripaludis* and *M. thermolithotrophicus* can also use N_2 ; *M. maripaludis* can use alanine; and *M. vannieli* can use purines as sole nitrogen sources (DeMoll and Tsai, 1986). The methanococci utilize H_2S and elemental sulfur as sole sulfur sources. In addition to these, *M. thermolithotrophicus* utilizes thiosulfate, sulfite, and sulfate as sole sulfur sources (Daniels et al., 1986). The methanococci are not known to use organic sulfur sources, although *M. voltae* readily assimilates coenzyme M (Santoro and Konisky, 1987).

The methanococci appear to be restricted to marine environments. *M. vannieli* was isolated from a formate enrichment of black mud from San Francisco Bay, CA, USA. Only a single strain has been described. A number of strains of *M. voltae* and *M. maripaludis* were isolated from estuarine sediments and *Spartina alterniflora* marshes. The source of "*M. aeolicus*" has not been reported. The single described strain of *M. thermolithotrophicus* was isolated from geothermally heated sediments at Stufe di Nerone near Naples, Italy. Three strains of *M. jannaschii* were isolated from hydrothermal vents in the East Pacific Rise and the Guaymas Basin.

The Family Methanomicrobiaceae

The family Methanomicrobiaceae contains H_2 -utilizing cocci (*Methanogenium* and *Methanoculleus*), as well as disc-shaped (*Methanoplanus*), rod-shaped (*Methanomicrobium* and *Methanocaldococcus*), and spiral-shaped (*Methanospirillum*) methanogens. The phylogenetic tree is shown in Fig. 4. The coccoid Methanomicrobiaceae have protein S-layers, which cause them to stain Gram-negative and to be osmotically fragile. Cells lyse when exposed to dilute detergents or hypotonic shock. They all grow by reducing CO_2 , using H_2 and formate as electron donors. Acetate is generally required as a growth factor and peptones are often required or stimulatory as well; many strains require tungstate and nickel. Motility is rare, although electron micrographs indicate that several strains have flagella.

METHANOGENIUM AND METHANOCULLEUS. Nine species have been described within the genera *Methanogenium* and *Methanoculleus* (Table 11).

Fig. 4. Phylogenetic tree for the families *Methanomicrobiaceae* (spirillum group) and *Methanosarcinaceae* (sarcina group) based upon 16S rRNA sequences. *Msar.*, *Methanosarcina*; *Mlo.*, *Methanolobus*; *Mco.*, *Methanococcoides*; SF1 is a strain closely related to *Methanohalophilus mahii*; *Mha.*, *Methanohalophilus*; *Msae.*, *Methanosaeta*; *Mg.*, *Methanogenium*; *Mpl.*, *Methanoplanus*; *Mm.*, *Methanomicrobium*; *Mcul.*, *Methanoculleus*; *Mcr.*, *Methanocorpusculum*; *Ms.*, *Methanospirillum*; and *Mc.*, *Methanococcus*. (P. E. Rouvière and C. R. Woese, personal communication.)

In addition, *Methanogenium aggregans*, which is not listed, has recently been reclassified as *Methanocorpusculum* (Xun et al., 1989). Since the time when the genus *Methanogenium* was originally defined (Romesser et al., 1979), the circumscription of the genus has gradually and informally been broadened to include most coccoid, H_2 - and formate-utilizing methanogens that did not fit into the genus *Methanococcus*. Recently, these organisms were shown to fall into three phylogenetic groups (Xun et al., 1989): The first group, comprised of *Methanogenium cariaci* (the type species) (Fig. 5) and *M. organophilum*, includes the two species with a requirement for concentrations of NaCl close to that found in seawater. The second group, which is the most diverse physiologically, has been reclassified as a new genus called *Methanoculleus* (Maestrojuán et al., 1990). This group includes both mesophiles and thermophiles that require low concentrations of NaCl for optimal growth but may also be halotolerant. The species in this group are *Methanoculleus marisnigri*, *M. bourgense*, *M. olentangyi*, and *M. thermophilicum*. *Methanogenium tationis* constitutes the third group, and, on the basis of DNA-DNA hybridization, it is not closely related to other species of *Methanogenium* or *Methanoculleus*. However, at this time, it has not been reclassified. Likewise, the phylogenetic positions of "*M. frittonii*" and "*M. liminatans*" have not been examined in detail at this time.

The substrates for methanogenesis for all nine species in this group include $H_2 + CO_2$ and formate. Four species, *M. marisnigri*, *M. thermophilicum* (one out of three strains), *M. organo-*

Fig. 5. *Methanogenium cariaci*. Bar = 10 μm . (Courtesy of D. Boone.)

philum, and "*M. liminatans*," also utilize secondary alcohols. In addition, *M. organophilum* utilizes ethanol and 1-propanol. With the exception of "*M. frittonii*," all species require organic carbon supplements. Growth of *M. marisnigri* requires trypticase, and other peptones and yeast extract do not substitute. Peptones or yeast extract also stimulate the growth of *M. organophilum*, *M. thermophilicum*, *M. bourgense*, *M. tationis*, and "*M. frittonii*." For *M. tationis*, peptones can be partially replaced by a heavy metal solution. Certain strains of *M. thermophilicum* also have growth requirements for 4-aminobenzoate, biotin, nickel, molybdate, or tungstate.

Methanogenium and *Methanoculleus* species have been isolated from a variety of habitats. *M. cariaci*, *M. marisnigri*, *M. organophilum*, and *M. thermophilicum* were isolated from marine sediments. Additional strains of *M. thermophilicum* were also isolated from apple, potato, and kelp fed bioreactors. *M. bourgense* was isolated from a bioreactor fed tannery byproducts. *M. olentangyi* and "*M. frittonii*" were isolated from freshwater sediments. *M. tationis* was isolated from a moderately thermophilic solfataric pool in Chile. "*M. liminatans*" was isolated from treated industrial wastewater. Because the *Methanogenium* species grow more slowly than many other H_2 - and formate-utilizing methanogens, they may be missed during viable-cell enumerations. In broth culture, they may be overgrown by *Methanococcus* species or other organisms. In roll tubes, colonies of *Methanogenium* may take several weeks to become visible. The addition of 0.05–0.20 M NaCl may improve their recovery, however.

METHANOPLANUS. The cellular morphology of *Methanoplanus* is very distinctive (Table 12): by

phase contrast microscopy, *M. limicola* forms rectangular plates, and *M. endosymbiosus* is disc shaped. As the cells rotate in solution, they can be viewed on edge and appear as very thin rods. The dimensions of *M. limicola* are 0.07–0.30 μm thick, 1.6–2.8 μm long, and 1.5 μm wide. *M. endosymbiosus* is more disc shaped, with a diameter of 1.6–3.4 μm . Both species utilize H_2 and formate as substrates for methanogenesis. Best growth is obtained at neutral pH, mesophilic temperatures, and low NaCl (0.20–0.25 M). Growth of *M. limicola* is stimulated by yeast extract or peptones plus vitamins. The nutritional requirements of *M. endosymbiosus* have not been fully investigated. The cell envelope of each species contains an S-layer composed of hexagonally arranged subunits. The major proteins stain with the periodate-Schiff reagent and have apparent molecular weights of 143,000 and 110,000 for *M. limicola* and *M. endosymbiosus*, respectively. *M. limicola* was isolated from a small swamp formed from drilling wastes. *M. endosymbiosus* was isolated from a marine sapropelic ciliate.

METHANOMICROBIUM AND METHANOLACINIA. *Methanomicrobium* cells are short rods, but unlike the Methanobacteriaceae, they contain no pseudomurein (Table 12). The physical structure of the cell is apparently conferred by a protein cell wall. Exposure to low concentrations of sodium dodecyl sulfate and other detergents causes rapid cell lysis. Cells stain Gram-negative (Fig. 2). H_2 and formate are substrates for methanogenesis. Growth is most rapid at temperatures near 40°C and between pH 6.1 to 6.9. *M. mobile* has exceptionally complex nutritional requirements and was isolated from the rumen of a fistulated heifer fed alfalfa hay, where it was very abundant.

Methanolacinia cells are pleomorphic, and they have been described both as short rods and as highly irregular and lobed cocci. Although flagella have been observed, motility has not. Until recently, the single species, *M. paynteri*, was classified in the genus *Methanomicrobium*. The single isolate utilizes H_2 and secondary alcohols as substrates for methanogenesis (Zellner and Winter, 1987a). Growth is stimulated by yeast extract, trypticase, and 0.15 M NaCl. The temperature and pH optima are 40°C and pH 7, respectively. *M. paynteri* may readily be distinguished from *Methanomicrobium mobile* by differences in its polyamine and lipid content (Zellner et al., 1989b). *Methanolacinia paynteri* was isolated from marine sediment.

Methanospirillum

Methanospirillum is a spiral-shaped cell (0.4 μm wide by 7.4–10 μm long), twisted into a gentle

Fig. 6. *Methanospirillum* (A) Long, wavy filaments. (B) Individual cells. (From Mah and Smith, 1981.)

helix (Table 12). The helical shape may be conferred by a sheath that surrounds the cell (Patel et al., 1986). Cells may form either long chains, or filaments, encased by a continuous sheath or be single (Fig. 6; Patel et al., 1979). *M. hungatei* also lyses slowly in 1% sodium dodecyl sulfate. Colonies in solidified medium have a wavy appearance, probably conferred by the helical shape of the cells. *M. hungatei* is the only species in this genus that has been described. $\text{H}_2 + \text{CO}_2$ and formate are substrates for methanogenesis, and some strains use 2-propanol and 2-butanol as well. The temperature optimum for growth is 35–40°C. Acetate is required or stimulatory. In addition, one strain is stimulated by peptones and B-vitamins. *M. hungatei* has been isolated from sewage sludge and a pear-waste digester.

The Family Methanocorpusculaceae

This family contains only one genus, *Methanocorpusculum*, and is more closely related to the Methanomicrobiaceae than to any other families

of methanogens. The five species of the genus are very small, irregular cocci that utilize H_2 and formate as substrates for methanogenesis (Table 13). *M. parvum* and *M. bavaricum* also utilize secondary alcohols (Zellner and Winter, 1987a; Zellner et al., 1989c). The diameter of the cells varies somewhat with the growth conditions. For *M. parvum*, the cell diameter is less than or equal to 1 μm . The cell diameters of *M. labreanum* and *M. aggregans* vary from about 0.5–2.0 μm . *M. aggregans* also forms large, multicellular clumps. All species have complex nutritional requirements for peptones, rumen fluid, or yeast extract. In addition, *M. labreanum* is stimulated by acetate, and *M. parvum* requires 1 μM tungstate. *M. parvum* was isolated from a whey digester and is unusually halotolerant. *M. aggregans* was isolated from a sewage digester. *M. labreanum* was isolated from lake sediment near the La Brea Tar Pits, California. *M. sinense* was isolated from a biogas plant in Chengdu, China. *M. bavaricum* was isolated from a wastewater treatment pond in Germany.

The Family Methanosarcinaceae

All of the aceticlastic methanogens belong to this family, as well as all methanogens that disproportionate methanol, methylamines, or other methyl-containing compounds. The only other species that catabolize methanol are *Methanospira* species, which require H_2 to reduce it to methane. The family Methanosarcinaceae can be divided into three physiological and morphological types: 1) the genus *Methanosarcina*, which contains coccoid and pseudosarcinal cells and can disproportionate methanol and catabolize acetate and $H_2 + CO_2$; 2) the genus *Methanosaeta*, which grows only by the aceticlastic reaction; 3) the halophilic, methylotrophic organisms of the genera *Methanohalophilus*, *Methanohalobium*, *Methanohalobium*, and *Methanohalophilus*. Phylogenetically, only the first of these groups is composed of closely related species (Fig. 4).

METHANOSARCINA. *Methanosarcina* species disproportionate methanol and methylamines, forming CH_4 and CO_2 in a ratio of approximately 3:1 (Table 14). Most strains also use acetate, and most also use H_2 to reduce either CO_2 or methanol to CH_4 . Formate is never used. Cells appear to have a protein cell wall adjacent to the cytoplasmic membrane. External to the protein wall, many strains have a layer of methanochondroitin, referred to as a matrix. Cells without the matrix are individual, irregular cocci, but when the matrix is present, packets or pseudoparenchyma are formed (Fig. 7). Within the packets, the cells are irregular in shape, the division

Fig. 7. *Methanosarcina barkeri* strain MS. Bar = 10 μm . (Courtesy of D. Boone.)

planes are not always perpendicular, and the volume of the daughter cells is not always equal. Three morphotypes of *Methanosarcina* have been described. Morphotype 1 includes some strains of *M. barkeri* that form aggregates of packets of cocci termed pseudoparenchyma, which may be visible to the unaided eye (Zhilina, 1976). Morphotype 2 includes *M. vacuolata*, which forms small packets and tends to remain dispersed and settles slowly in liquid medium. Morphotype 3 includes *M. mazei*, which forms single cocci, packets of pseudococci, and large macrocysts (Zhilina and Zavarzin, 1979b; Robinson, 1986).

While morphology and substrate range are important characteristics of *Methanosarcina*, they are not always reliable indicators of species differences. These characteristics frequently vary when closely related strains are tested, or the same strain may give varied results under different conditions. For example, a single enzyme may be responsible for changing large pseudoparenchymal aggregates into individual coccoid cells, and this enzyme may be produced only under certain growth conditions (Harris, 1987; Sowers and Gunsalus, 1988; Xun et al., 1988). The ability to use substrates often depends on the conditions of the inoculum (Boone et al., 1987), and the ability to form gas vacuoles is not a constant characteristic of strains (R. A. Mah, personal communication). Thus, variations in these characteristics within species may be commonplace, and they may not always be reliable for the placement of strains into species.

The diameter of the cocci or cells within the aggregates is generally 1–2 μm , although both smaller and larger cells are observed. The cells of *Methanosarcina* are nonmotile, and in those species that stain Gram negative, the cells lyse in the presence of sodium dodecyl sulfate. Cells of

M. vacuolata contain numerous gas vacuoles tightly clustered in the cytoplasm. The *Methanosarcina* do not require additional carbon sources, and species that use $H_2 + CO_2$ as a substrate for methanogenesis can grow autotrophically. However, peptones or yeast extract are stimulatory for *M. mazei*, *M. vacuolata*, and *M. frisia*, and riboflavin is stimulatory or required for at least one strain of *M. barkeri* (Scherer and Sahm, 1981a). The chemicals 4-aminobenzoate and calcium chloride (0.7 mM) are required for growth of *M. thermophila*. *M. barkeri* grows with dinitrogen as its sole nitrogen source (Bomar et al., 1985; Murray and Zinder, 1984). Methionine, cysteine, thiosulfate, and elemental sulfur are also sulfur sources for some strains of *M. barkeri* (Mazumder et al., 1986; Scherer and Sahm, 1981b).

M. barkeri, *M. mazei*, *M. thermophila*, and *M. vacuolata* were isolated from anaerobic digestors. *M. barkeri* is also found in freshwater and marine sediments, rumens of ungulates, and animal-waste lagoons. *M. mazei* has been found in garden soil, sewage sludge, and various other sources. *M. vacuolata* is common in freshwater sediments, marshes and wetlands. *M. acetivorans* and *M. frisia* were isolated from marine sediments and for optimal growth require 0.2 and 0.3–0.4 M NaCl, respectively. *M. acetivorans* also requires 0.05–0.10 M magnesium for optimal growth. In addition to the type strain of *M. thermophila*, two strains of thermophilic *Methanosarcina* have been described (Ollivier et al., 1984; Touzel et al., 1985), whose nutritional characteristics resemble those of *M. thermophila*. However, both the pseudoparenchymal and coccoid morphologies are present, and the taxonomic status of these latter strains is uncertain.

OBLIGATELY METHYLOTROPHIC COCCI. Eight species and five genera of obligately methylotrophic, irregular cocci have been described (Table 15). In addition, two species of *Methanobolus*, *M. siciliae* and *M. vulcani*, have been proposed, but a complete description is unavailable (Stetter, 1989). At present, the taxonomy of these organisms is uncertain. Therefore, they have been arranged in the table in the order of increasing optimal salinity for growth, which varies from marine to extremely halophilic. Phylogenetic studies by RNA sequencing, RNA-DNA hybridization and DNA-DNA hybridization suggest that *Methanococcoides methylutens*, *Methanobolus tindarius*, *Methanohalophilus zhilinae*, *M. mahii*, and *Methanohalobium evestigatum* probably represent five different genera rather than only four (Sowers et al., 1984b; Chumakov et al., 1987; also see Fig. 4). The placement of the three remaining species listed in Table 15 is not known.

Fig. 8. *Methanohalobium evestigatum*. (A) Cells and aggregates, anoptal contrast Reichert. Bar = 5 μ m. (B) Ultrathin section of late exponential phase cells. Layers of the envelope slip from the cell surface. Nuclear region and star-shaped granules (possibly glycogen) are present. Bar = 0.5 μ m. (Courtesy of T. Zhilina.)

These species grow by disproportionation of methanol, methylamines, and other C-1 compounds. H_2 , formate, and acetate are not substrates. Cells are small irregular cocci, and some species form small aggregates. Cells of *M. evestigatum* are flat and polygonal, and they often occur in sheets (Fig. 8). *Methanococcus halophilus* produces slime. All the species are nonmotile, except for *Methanobolus tindarius*, which has monotrichous flagellation. With exception of *Methanohalobium evestigatum*, they stain Gram negative and lyse rapidly in dilute sodium dodecyl sulfate (or Sarkosyl for *Methanococcus halophilus*). These species are mesophilic, and their temperature optima are 30–35°C with three exceptions: the temperature optimum for *Methanobolus tindarius* is 25°C; the temperature optimum for *Methanohalophilus zhilinae* is 45°C; the temperature optimum for *Methanohalobium*

evestigatum is 50°C. *Methanohalophilus zhilinae* and *M. oregonense* are also alkalophilic.

In addition to NaCl, *M. euhalobius* and *M. mahii* require high concentrations of magnesium and calcium for good growth. *M. methylutens* and *M. oregonense* require high concentrations of magnesium. Although the organic growth factors of the type strain of *M. mahii* are not known, strain SF-1, which appears to be closely related, requires yeast extract. Vitamins stimulate the growth of *M. tindarius* and peptones that of *M. zhilinae*. In contrast, greater than 0.05% yeast extract or peptones inhibit the growth of *M. halophilus* and *M. evestigatum*.

M. tindarius and *M. methylutens* were isolated from marine sediments. *M. mahii*, *Halomethanococcus doii*, *M. zhilinae*, and *M. oregonense* were isolated from sediments of saline or saline and alkaline lakes. *M. halophilus* was isolated from a sample containing the cyanobacterial mat and associated mud of a stromatolite in Shark Bay, Australia. *M. evestigatum* was isolated from a cyanobacterial mat in a hypersaline lagoon close to Arabat, Sivash. *M. euhalobius* was isolated from the stratal liquid of an exploratory oil well.

METHANOSAETA. In contrast to the other genera of the family Methanosarcinaceae, which are coccoid, the species of *Methanosaeta* (formerly called *Methanothrix*) are sheathed rods. These organisms grow only by the acetoclastic reaction (Table 16). Acetate is the only substrate for methanogenesis, and H₂, formate, and methyl compounds are not utilized. Because of their very long generation time, 1 to 3 days under optimal conditions, pure cultures have been difficult to obtain. For instance, the original culture of “*M. soehngenii*” is not pure, and vancomycin is required to suppress the growth of contaminants (Patel and Sprott, 1990; Touzel et al., 1988). Likewise, the description of *M. thermoacetophila* is based upon a monoculture, although a pure culture has recently been obtained. Two other pure cultures have also been described. *M. concilii* appears to be closely related to the methanogen in “*M. soehngenii*” cultures, and strain CALS-1 appears to be similar to *M. thermoacetophila*, but insufficient cell mass has been obtained to complete the species description.

Methanosaeta is a short, fat, nonmotile rod with flat ends. Cells stain Gram negative and are sheathed. Except for CALS-1, stationary cultures may form long filaments with a contiguous sheath (Fig. 9). The filaments may form large bundles, mats, or flocs. In shaken cultures, the filaments tend to fragment into short filaments or individual cells. *M. thermoacetophila* and CALS-1 contain gas vacuoles and *M. concilii* produces a capsule.

Fig. 9. *Methanosaeta concilii*. Bar = 10 μ m. (Courtesy of D. Boone.)

Marine or halophilic species have not been described, and NaCl does not need to be added to the media above trace amounts. The pH optima of “*M. soehngenii*,” *M. concilii*, and CALS-1 are 7.4–7.8, 7.1–7.5, and 6.5, respectively. Yeast extract inhibits the growth of *M. concilii*, and penicillin inhibits the growth of “*M. soehngenii*” and *M. thermoacetophila*. CALS-1 is very sensitive to the reducing agents in the medium, and 1 mM sulfide and 1 mM 2-mercaptoethanesulfonate appear to be optimal.

Methanosaeta is widely distributed in nature. Its distinctive morphology has allowed it to be identified in sewage sludge, digestors, animal wastes, and sanitary landfills. Monocultures of the thermophiles have been obtained from different types of thermophilic digestors and thermal sediments. “*M. soehngenii*” and CALS-1 were obtained from sludge digestors. *M. concilii* was obtained from a pear waste digester. *M. thermoacetophila* was obtained from the sediments of a thermal lake.

Methanogens of Uncertain Affiliation

A thermophile, TAM, that morphologically resembles *Methanosaeta* has been isolated from a sewage sludge digester (Ahring and Westermann, 1984, 1985). Cells are 0.8–1 μ m wide and 4–5 μ m in length, and they normally form short filaments. A sheath is present. Cells stain Gram positive to variable. In contrast to *Methanosaeta*, H₂ + CO₂ and formate are substrates for methanogenesis in addition to acetate. Growth factors are not required during growth on acetate. The pH optimum is 7.3–7.5, and the temperature optimum is 60°C. Penicillin and other typical eubacterial antibiotics are inhibitory at high concentrations.

The isolation of a wall-less methanogen, "*Methanoplasma elizabethii*," from an anaerobic chemostat fed glucose was reported but not confirmed (Rose and Pirt, 1981). "*M. elizabethii*" uses $H_2 + CO_2$ and formate as substrates for methanogenesis.

Biochemical and Physiological Properties

Coenzymes of Methanogenesis

Methanogens contain many novel coenzymes that are associated with the biochemistry of

methane synthesis. Thus, what should be a chemically simple reduction of C-1 compounds to methane is biochemically complex. Because the structure and synthesis of many of the coenzymes have recently been reviewed (Jones et al., 1987), only the most recent citations are included below.

Methanofuran (MFR) (Fig. 10A) functions as a formyl carrier in methanogenesis. It is required for the initial activation of CO_2 to formyl-MFR, the first stable product of CO_2 reduction. MFR has been found in all methanogens examined at levels ranging from 0.5 to 2.5 mg per kg dry weight of cells. At least five different forms of methanofuran exist among the methanogens

A. Methanofuran

B. Tetrahydromethanopterin

C. Coenzyme M

D. Methyl coenzyme M

E. 7-Mercaptoheptanoylthreonine phosphate

F. Coenzyme F_{430}

G. Coenzyme F_{420} (reduced)

Fig. 10. The seven coenzymes of methanogenesis.

(White, 1988). This coenzyme has not been detected in either nonmethanogenic archaeobacteria, with the exception of *Archaeoglobus fulgidus*, or eubacteria. The 2,4-disubstituted furan moiety and the 4,5-dicarboxy octanoate moiety are unique structures in nature.

Tetrahydromethanopterin (H_4MPT) is a one-carbon carrier similar to folate in structure and function (Fig. 10B). Likewise, biosynthesis of H_4MPT is also similar to tetrahydrofolate biosynthesis in eubacteria. The coenzyme was first noticed as a yellow fluorescent compound (YFC) that was rapidly labeled by $^{14}CO_2$ in cell extracts (Daniels and Zeikus, 1978). H_4MPT is also required for several biosynthetic reactions that are folate-dependent in eubacteria, such as serine hydroxymethyltransferase.

A third one-carbon carrier unique to methanogens is coenzyme M (HS-CoM) (Fig. 10C), which chemically is 2-mercaptoethanesulfonic acid. HS-CoM serves as the terminal carbon carrier in methanogenesis where methyl coenzyme M (CH_3 -S-CoM) (Fig. 10D) is reduced to CH_4 . Since HS-CoM has been found in all methanogens examined, it may serve as a sensitive biomarker for the qualitative identification of methanogens in various ecological niches.

7-Mercaptoheptanoylthreonine phosphate (HS-HTP) (Fig. 10E) is a colorless coenzyme that is required for the final step of methanogenesis. This coenzyme is the electron donor for CH_3 -S-CoM reduction, and it is proposed to participate in the energy-conserving step of methanogenesis (Ellermann et al., 1988). It is also required for the activation of CO_2 reduction (Bobik and Wolfe, 1988). HS-HTP is probably biosynthesized from α -ketoglutarate by repeated α -keto-acid chain elongation in a process similar to the aminoadipate pathway of lysine biosynthesis in eubacteria (White, 1989).

Coenzyme F_{430} (Fig. 10F) is a nickel-containing coenzyme required for the final step of methanogenesis, and it is tightly associated with component C of the methylreductase system. The coenzyme was first noticed in cell extracts by J. LeGall and reported by Gunsalus and Wolfe (1978). It is interesting to note that biosynthesis of coenzyme F_{430} proceeds from 5-aminolevulinate via uroporphyrinogen III, which indicates that nickel tetrapyrroles share a common biosynthetic pathway with all other porphyrinoid compounds (Pfaltz et al., 1987).

Autofluorescence of methanogenic bacteria is largely due to the presence of high levels of coenzyme F_{420} (Fig. 10G). Coenzyme F_{420} is ubiquitous among methanogens, and it is found at low levels in some other organisms. It is a deazaflavin and participates in two-electron transfer reactions. In this regard, it functions in a manner analogous to NADH, but its redox potential of

–340 to –350 mV is lower. The coenzyme is an electron donor in methanogenesis. In addition, coenzyme F_{420} is coupled to hydrogenase, formate dehydrogenase, carbon monoxide dehydrogenase, NADP⁺ reductase, pyruvate synthase, and α -ketoglutarate synthase (Keltjens and van der Drift, 1986).

In addition to the novel coenzymes described above, methanogens contain a number of common vitamins (Noll and Barber, 1988). These include thiamine, riboflavin, pyridoxine, corrinoids, biotin, niacin, and pantothenate. Flavins are known to function as electron carriers for hydrogenase, NADH reductase, formate dehydrogenase, and the methylreductase system in *Methanobacterium*. Many methanogens contain abundant amounts of unusual corrinoids, with factor III or pseudovitamin B₁₂ being the most predominant (Stupperich and Kräutler, 1988). Corrinoids have also been implicated in methane synthesis, where they function as methyl carriers. In contrast, folates are absent or present in very small amounts in methanogens (Worrell et al., 1988). Presumably, methanopterin substitutes for folate as a methyl carrier. Methanogens have also been found to contain ferredoxin, thioredoxin, and cytochromes *b* and *c*. Ferredoxin is abundant in the acetoclastic methanogens, where it is coupled with the catabolic carbon monoxide dehydrogenase, and has been isolated from *Methanococcus thermolithotrophicus* (Hatchikian et al., 1989; Terlesky and Ferry, 1988a). Thioredoxin was isolated from *Methanobacterium thermoautotrophicum*, but its function is unknown (Schlicht et al., 1985). Cytochromes function as electron carriers during methanogenesis from methanol, methylamines, and acetate. They are implicated in the oxidation of these substrates during their disproportionation (Terlesky and Ferry, 1988b). In support of this hypothesis, cytochromes are absent from *Methanospaera*, which must use H_2 as a reductant during growth on methanol.

The Pathway of Methanogenesis

The pathway of methanogenesis has been extensively reviewed (Jones et al., 1987; Rouvière et al., 1988; Rouvière and Wolfe, 1988). The reduction of CO_2 to CH_4 involves seven steps. The source of electrons may be either H_2 via hydrogenase or formate via formate dehydrogenase. Formate itself does not appear to be an intermediate. Initially, CO_2 is activated to form formylmethanofuran. Next, the formyl group is transferred to H_4MPT , where it is reduced to the methylene and methyl levels. Last, the methyl group is transferred to coenzyme M and reduced to methane by the methylreductase system.

Fig. 11. The pathway of methane formation from acetate, methanol, and CO_2 . Methyl-CoM is the key intermediate for the reduction of CO_2 , acetate, and methanol to methane. The numbers refer to the seven steps of the cycle. (Adapted from Rouvière et al., 1988.)

The first step of CO_2 activation is not clearly understood (Fig. 11, step 1). It requires ATP, but not in stoichiometric amounts. The energy for the reaction is derived from the final step of methane formation (Fig. 11, step 7). This conclusion is supported by the observation that CO_2 activation in vitro requires small amounts of $\text{CH}_3\text{-S-CoM}$ or a strong reductant such as titanium citrate (Bobik and Wolfe, 1989). The formyl group is transferred from MFR to H_4MPT by formylmethanofuran:tetrahydromethanopterin formyltransferase (Fig. 11, step 2). The formyl group then undergoes sequential reduction beginning with its conversion to 5,10-methenyl- H_4MPT by the enzyme 5,10-methenyltetrahydromethanopterin cyclohydrolase (Fig. 11, step 3). The methenyl group is reduced by coenzyme F_{420} in a reaction catalyzed by methylenetetrahydromethanopterin:coenzyme F_{420} oxidoreductase to yield 5,10-methylene- H_4MPT (Fig. 11, step 4). The enzymes for steps 5 and 6 have not been purified to homogeneity. Step 5 is presumably catalyzed by methylene- H_4MPT reductase to yield methyl- H_4MPT . Conversion of methyl- H_4MPT to $\text{CH}_3\text{-S-CoM}$ involves a corrinoid-containing methyltransferase (Kengen et al., 1988; Fig. 11, step 6).

The terminal reaction, catalyzed by the methylreductase system, represents the completion of the cycle with the release of CH_4 and the activation of CO_2 (Fig. 11, step 7). The methylreductase system catalyzes the conversion of $\text{CH}_3\text{-S-CoM}$ and HS-HTP to CH_4 and CoM-S-S-HTP . Although the exact process is not known, methane formation is also coupled to ATP synthesis via a chemiosmotic mechanism (Blaut and Gottschalk, 1985). However, this coupling may occur during the reduction of the disulfide bond of CoM-S-S-HTP rather than during the reduction of $\text{CH}_3\text{-S-CoM}$ (Ellermann et al., 1988). CoM-S-S-HTP is also required for the coupling

of $\text{CH}_3\text{-S-CoM}$ reduction to CO_2 activation (Bobik and Wolfe, 1988).

The process of $\text{CH}_3\text{-S-CoM}$ reduction is complex and requires four protein components and at least three unique coenzymes. Components A1, A2, A3, and C are proteinaceous. A1 and A3 are oxygen-labile and have not been highly purified. A1 has coenzyme F_{420} -dependent hydrogenase activity and is probably required for the reduction of CoM-S-S-HTP (Rouvière et al., 1988). A3 has been resolved into two fractions: A3a and A3b. A3a is a large iron-sulfur protein, which may be involved in providing electrons for component C. A3b has methyl viologen-dependent hydrogenase activity (Rouvière and Wolfe, 1989). A2 is an oxygen-stable component and has been purified to homogeneity. A2 and A3 are probably required for the ATP-dependent reductive activation of component C (Rouvière et al., 1988). Component C is an oxygen-stable protein, which is the methyl-S-CoM methylreductase proper. It contains 2 moles of F_{430} and 2 moles of HS-CoM per mole of enzyme, and it has three types of subunits with a stoichiometry of $\alpha_2\beta_2\gamma_2$. The enzyme represents about 10% of the total cellular protein. The genes for component C are organized into a five-gene cluster, *mcrBDCGA*. The primary sequences of these genes are highly conserved in all methanogens examined. Subunits α , β , and γ are coded for by *mcrA*, *mcrB*, and *mcrG*, respectively. The functions of *mcrC* and *mcrD* are unknown (Allmansberger et al., 1989; Weil et al., 1989).

The methylreductase system is also required for methanogenesis from substrates other than CO_2 (Fig. 11). During the catabolism of acetate, the methyl and carboxyl groups are converted to CH_4 and CO_2 , respectively, via an acetoclastic reaction. This reaction involves the initial activation of acetate as acetyl-CoA (Terlesky et al.,

Fig. 12. The two acetogenic pathways for the autotrophic fixation of CO_2 to acetyl-CoA in (A) *Clostridium thermoaceticum* and (B) *Methanobacterium thermoautotrophicum*. THF, tetrahydrofolate; E1, carbon monoxide dehydrogenase; E2, the corrinoid enzyme involved in methyl transfer. (Adapted from Jones et al., 1987.)

1987). The carbon-carbon bond is then cleaved by the carbon monoxide dehydrogenase system, producing HS-CoA, an enzyme-bound CO, and a methyl group. The methyl group is transferred to HS-CoM via H_4MPT with the aid of an unidentified corrinoid enzyme (Fischer and Thauer, 1989; van de Wijngaard et al., 1988). Oxidation of the enzyme-bound CO to H_2 and CO_2 provides electrons for the reduction of $\text{CH}_3\text{-S-CoM}$ to CH_4 (Terlesky and Ferry, 1988b; Bott and Thauer, 1989).

Methane is also produced from the catabolism of methanol and methylamines. Methanogenesis from methanol can occur in two different ways depending on the electron donor: 1) if it is H_2 , the methyl group of methanol is transferred to HS-CoM via two methyltransferases (MT1 and MT2). The former contains an oxygen-sensitive cobamide moiety as a methyl carrier. $\text{CH}_3\text{-S-CoM}$ is then reduced to CH_4 by H_2 . 2) When H_2 is absent, some of the methanol is oxidized in a disproportionation reaction to serve as reductant for the methylreductase system. Likewise, for methylamines the methyl group is either reduced to CH_4 or oxidized to CO_2 . After growth in the presence of trimethylamine, *Methanosarcina barkeri* contains a trimethylamine:HS-coenzyme M methyltransferase similar to the methanol-induced methyltransferases.

Carbon Metabolism

Methanogens use only simple organic or inorganic carbon compounds as energy sources.

About one-half of methanogens are also capable of autotrophic growth, and they obtain all their organic carbon from the assimilation of CO_2 . The proposed methanogenic autotrophic pathway, the Ljungdahl-Wood pathway, is unlike classic autotrophic CO_2 fixation (the ribulose biphosphate pathway) since the primary intermediate is acetyl-CoA. The Ljungdahl-Wood pathway was discovered in the acetogenic clostridia and has been extensively studied in *Clostridium thermoaceticum* (Fig. 12A; Ljungdahl, 1986; Wood et al., 1986). The key enzyme is a nickel-containing carbon monoxide dehydrogenase system (CODH). In methanogens, the one-carbon carrier of the clostridial pathway, folate, is replaced by tetrahydromethanopterin (H_4MPT) (Fig. 12B; Fuchs, 1986). The pathways of autotrophy and methanogenesis are closely linked, and they share common intermediates. Thus, many of the methanogenic coenzymes serve both anabolic and catabolic functions. CO_2 is first reduced to formyl-MFR. The formyl group is then transferred to H_4MPT and reduced to a methyl group. At this point the anabolic and catabolic pathways diverge. The subsequent transfer of this methyl group to HS-CoA is believed to involve a cobamide-containing protein. The carboxyl moiety is derived from CO_2 via CODH and a carbonylation reaction. At this step the carboxyl group freely exchanges with CO in the environment. Although acetogenesis in methanogens appears similar to the pathway in eubacteria, it is distinctive due to the absence of folates and the lack of an ATP requirement for the activation of CO_2 .

Fig. 13. The pathways of carbon assimilation in methanogens. Solid lines represent the incomplete reductive TCA cycle found in *Methanobacterium thermoautotrophicum* and *Methanococcus maripaludis*. Broken arrows represent the incomplete oxidative TCA cycle found in *Methanosarcina barkeri*. (Shieh and Whitman, 1987.)

Methanogens utilize the anabolic tricarboxylic acid (TCA) cycle to synthesize cell carbon from acetyl-CoA (Jones et al., 1987; Fig. 13). However, the exact nature of the cycle varies among different groups of methanogens. In *Methanosarcina barkeri*, α -ketoglutarate is formed by an oxidative branch. *Methanospirillum*, *Methanococcus*, and *Methanobacterium* utilize the reductive or reverse pathway (Fuchs and Stupperich, 1986). Hexoses are derived from acetate by gluconeogenesis. The major storage product for carbohydrates is glycogen. Very little information is available on how this polysaccharide reserve is used, since no known methanogens can catabolize exogenous sugars. *Methanosarcina thermophila* is capable of mobilizing its reserves and actually producing small amounts of acetate when starved for acetate (Murray and Zinder, 1987). Likewise, *Methanlobus* produces small amounts of methane upon mobilization of its glycogen reserves (König et al., 1985).

Heterotrophic methanogens rely on exogenous acetate for growth. An incomplete, reductive TCA cycle has been found in *Methanococcus voltae*, indicating the presence of a mechanism of anabolic carbon metabolism that is similar to the

one found in autotrophic methanogens (Shieh and Whitman, 1987).

Nitrogen and Sulfur Metabolism

Ammonia serves as the sole nitrogen source during autotrophic growth, although some methanogens are capable of utilizing a variety of other nitrogenous compounds. The presence of glutamate synthase in *Methanobacterium thermoautotrophicum* enables it to use glutamate as a sole nitrogen source (Kenealy et al., 1982). Some methanogens have also been shown to utilize urea, purines, and dinitrogen (Bhatnagar et al., 1984; DeMoll and Tsai, 1986; Lobo and Zinder, 1988). Nitrogen fixation (diazotrophy) in *Methanosarcina barkeri* requires molybdenum and is inhibited by tungsten, like in the eubacteria (Lobo and Zinder, 1988). For at least one strain, vanadium will substitute for molybdenum (Scherer, 1989). The rate of biosynthesis of the nitrogenase enzyme decreases in the presence of ammonia. In addition, the decrease in growth rate suggests diazotrophy is an energetically expensive process, as it is in eubacteria. Although the enzyme has not been purified, genetic evidence suggests sequence homology between methanogen and eubacterial nitrogenase genes (Sibold et al., 1985).

Sulfide is commonly included as a reductant and a sulfur source in the cultivation of methanogens. However, several species have the ability to use other inorganic sulfur sources, including elemental sulfur, sulfate, sulfite, and thiosulfate (Daniels et al., 1986). The observed reduction of sulfate and sulfite is strictly assimilatory in methanogens. Therefore, it is unlikely that these compounds can serve as alternate electron acceptors. Organic sulfur sources include methionine and cysteine (Mazumder et al., 1986; Scherer and Sahm, 1981b).

Cell Envelope Structure

The diversity of the methanogenic bacteria is demonstrated by the large differences in cell envelope structure. These topics are reviewed in detail by König (1988). The three known types of cell walls are composed of pseudomurein, protein, and heteropolysaccharide.

The cell wall of the Methanobacteriaceae (Fig. 14A and B) is composed of pseudomurein, a peptidoglycan analogous to eubacterial murein (Fig. 15). Pseudomurein contains L-talosaminuronic acid instead of muramic acid, $\beta(1-3)$ linkages instead of $\beta(1-4)$ linkages in the polysaccharide backbone, and different sequences of crosslinking amino acids. When these differences are considered, it is obvious

Fig. 14. (A) *Methanobacterium thermoautotrophicum* prepared by freeze-substitution in osmium-acetone. The wall (W) averages 15–16 nm in thickness and the membrane (PM) 8 nm. (B) *M. thermoautotrophicum* prepared by chemical fixation: glutaraldehyde-formaldehyde mixture followed by osmium tetroxide. Appearance is very similar to freeze-substituted cell (A and B from Aldrich et al., 1987). (C) Chemically fixed cells of *Methanosarcina mazei*. Wall (CW) in this preparation appears expanded and fluffy. Small arrows indicate plasma membrane. (D) Freeze-fractured cell of *Methanosarcina barkeri*, showing large expanse of plasma membrane. Arrows delimit areas in which 12–13-nm-diameter intramembrane particles are arranged in regular arrays. (E) Cell of *M. barkeri* freeze-substituted in osmium-acetone. Wall (CW) appears dense and compact and measures about 20 nm in thickness. Trilaminar plasma membrane (PM) measures 7 nm. (F) Freeze-substituted cell of *M. mazei*. Wall and membrane are similar in size and appearance to those shown in (E). Bars = 100 nm. (Figs. 10C–F are courtesy of H.C. Aldrich.)

why *Methanobacterium* is resistant to the β -lactam antibiotics that inhibit eubacterial cell wall biosynthesis. Variation of pseudomurein structure within the Methanobacteriaceae occurs by alteration of the amino acid residues.

In contrast is the simple protein cell wall of the Methanococcaceae and most of the Methanomicrobiaceae. It consists of a crystalline arrangement of proteins or glycoproteins called an S-layer (Fig. 16). Unlike the rigid pseudomurein, the S-layer provides only limited support; therefore, the cells are osmotically fragile. The composition of the S-layer varies between genera based on the presence of glycosylation and between species by molecular weight of the subunits and antigenicity.

Members of the Methanosarcinaceae have a third type of cell wall, referred to as a heteropolysaccharide. The cell wall of *Methanosarcina* is composed of a polysaccharide matrix (Fig. 14 C–F), which is similar in structure to

eukaryotic chondroitin found in connective tissue. This polysaccharide stabilizes the cell aggregates formed by *Methanosarcina* species. The work of Aldrich et al. (1986) and Kreisl and Kandler (1986) has elucidated the chemical structure and arrangement of these polysaccharides on the cell surface as a loose matrix.

Methanosaeta (“*Methanothrix*”) and *Methanospirillum*, which are characteristically filamentous, have an outer protein sheath (Figs. 17 and 18). The cells are surrounded by an electron-dense inner wall of unknown composition and are separated by septa or plugs. The crystalline structure of the sheath has been studied in considerable detail by Beveridge et al. (1986) and Patel et al. (1986).

The cell membranes of methanogens are characterized by several unusual lipids (see reviews by De Rosa and Gambacorta, 1988; Langworthy, 1985; and Jones et al., 1987). In the majority of methanogens, the lipids are polar, either diphyt-

eubacteria. However, the process of transcription initiation and the termination sequences of certain genes are more similar to those found in eukaryotes. Moreover, the methanogen DNA polymerases that have been purified resemble both eubacterial and eukaryotic enzymes.

The DNA-dependent RNA polymerase of methanogens is genetically more closely related to the enzyme of eukaryotes than of eubacteria (Bernghofer et al., 1988). As a consequence, it might be expected that the methanogenic promoter sequences should also resemble eukaryotic sequences. Analysis of these sequences in numerous methanogen operons has revealed two conserved sequences. One has the consensus sequence of AAANNTTTATATA, where N represents any of the four nucleotides (Allmansberger et al., 1988). This sequence is found 25 bp upstream of the start site of transcription and resembles the "TATA" box found in eukaryotes. Binding of purified RNA polymerase to this sequence has been demonstrated in the methyl-reductase operon, *hisA*, and in the ribosomal RNA genes of *Methanococcus vannielii* (Thomm et al., 1989). The second conserved region, TGCAAGT, has been found at the start site of transcription of the ribosomal RNA genes. Termination of transcription has not been studied in detail. However, the gene *mcrA*, which codes for the α subunit of methylreductase, has a sequence analogous to the rho-independent terminator of eubacteria. In contrast, analysis of rRNA genes suggests a termination mechanism similar to that of eukaryotes, which use AT-rich sequences.

DNA polymerases in methanogens are heterogeneous. The enzyme purified from *Methanococcus vannielii* resembles the type A enzyme of eukaryotes in its sensitivity to the inhibitor aphidicolin (Zabel et al., 1987). In contrast, the purified enzyme of *Methanobacterium thermoautotrophicum* is resistant to aphidicolin and is similar to DNA polymerase I of *Escherichia coli* (Klimczak et al., 1986). The enzymes of *M. vannielii* and *M. thermoautotrophicum* also differ from each other in molecular weight.

The methanogen ribosome has a "typical" prokaryotic composition. The ribosome is 70S in size and dissociates into 30S and 50S subunits. The 30S subunit contains 16S rRNA, and the 50S subunit contains 5S and 23S rRNAs. A 5.8S rRNA, as found in eukaryotes, is not present. However, the structure of the methanogen ribosome differs from the eubacterial ribosome in that the 30S subunit has the characteristic archaeobacterial "bill," a small protrusion for which the function is unknown. A similar "bill" is also present on the eukaryotic 40S subunit (Lake et al., 1982). Ribosomal proteins of methanogens and other archaeobacteria are unusually acidic, in contrast to the basic ribosomal proteins of eubacteria and eukaryotes. However, the number of acidic ribosomal proteins correlates well with the internal K^+ concentration in the strains studied. The ribosomal proteins of *M. vannielii* are encoded by a transcriptional unit homologous in organization to the "spectinomycin operon" of *E. coli*. However, the deduced amino acid sequences of the methanogen proteins more closely resemble those of their eukaryotic homologs (Auer et al., 1989; Köpke and Wittmann-Liebold, 1989).

Sequencing of methanogen rRNAs has been instrumental in establishing their phylogenetic relationship with eubacteria and eukaryotes. The secondary structure of the methanogen 5S rRNA has characteristics of both the eubacterial and eukaryotic molecule. However, the methanogen rRNA molecule has characteristics that are unique to archaeobacteria. Sequence data for the 16S rRNA support the hypothesis of the extreme diversity of the archaeobacteria. The secondary structure of the methanogen 16S rRNA is more similar to that of the eubacterial structure than the eukaryotic secondary structure. Less information is available concerning the secondary structure of the 23S rRNA molecule. However, it does have characteristics of both the eubacterial and eukaryotic molecules. The genes for rRNA are arranged in a typical operon similar to that of eubacteria. The 16S, 23S, and 5S genes are closely linked and interspersed with several tRNA genes. *Methanococcus vannielii* and *M. voltae* also have unlinked 5S rRNA genes that are associated with tRNA-encoding genes.

Antibiotic Sensitivity and Resistance

The lack of sensitivity of methanogens and other archaeobacteria to most antibiotics is a reflection of their unique biochemical nature and has been reviewed previously (Böck and Kandler, 1985). Methanogens are resistant to many commonly used antibiotics simply because the specific target is not present. Therefore, comparison of the antibiotic sensitivity spectrum of methanogens

Table 17. Comparison of the antibiotic sensitivity of several species of methanogens, eubacteria and eukaryotes.

with those of eubacteria and eukaryotes can provide insight into their biochemical similarities and differences.

The differences in chemical structure of methanogen cell envelopes to those of eubacteria have been well established. These differences are supported by the lack of sensitivity of methanogens to many cell-wall inhibitors (Table 17). For example, *Methanobacterium thermoautotrophicum* is resistant to penicillin G, since the crosslinking of pseudomurein, which replaces peptidoglycan in the cell wall, is not inhibited by the antibiotic. However, antibiotics such as bacitracin, which inhibit the formation of lipid-bound precursors of murein in eubacteria, may inhibit formation of similar lipid-bound precursors involved in biosynthesis of lipids and glycoproteins in methanogens.

In addition to genetic homology, the antibiotic sensitivity of DNA-dependent RNA polymerase reflects the similarity of the methanogen enzyme to the eukaryotic enzyme (Table 17). Both enzymes are resistant to rifampicin, an antibiotic which inhibits RNA polymerase of eubacteria. The methanogen enzyme is also resistant to α -amanitin, which inhibits the type B and C polymerases of eukaryotes but not the type A enzyme.

Antibiotics that inhibit protein synthesis may block aminoacyl-tRNA synthesis, elongation, or translation. Pseudomonic acid is a potent inhibitor of *Methanococcus voltae* and inhibits isoleucyl-tRNA synthetase activity (Possot et al., 1988). Translation in methanogens is resistant to many of the antibiotics that inhibit translation by either the eubacterial 70S or eukaryotic 80S ribo-

somes (Böck and Kandler, 1985). While growth of the methanogens is sensitive to chloramphenicol, this inhibition is not due to an effect on protein synthesis. Instead, inhibition is probably due to the sensitivity of the particulate hydrogenase of *Methanobacterium* to this antibiotic and to other halogenated compounds. However, the elongation factor aEF-2 is sensitive to diphtheria toxin, which is also characteristic of the eukaryotic protein (Lechner et al., 1988). Sequence analysis of the genes encoding aEF-2 indicates that the methanogen enzyme is more closely related to its eukaryotic than its eubacterial homolog. In addition, all archaeobacterial aEF-2 genes examined possess a histidine residue that is posttranslationally modified to diphthamide, a phenomenon analogous to that of the eukaryotic EF-2. Translation in the methanogens is also resistant to most antibiotics in the streptomycin class of aminoglycosides, as well as to tetracycline and the macrolides. However, methanogens are sensitive to deoxystreptamine aminoglycosides, such as gentamycin and neomycin, as well as to virginiamycin. Therefore, the translation process in methanogens is different from that of the eubacterial process with respect to antibiotic sensitivity.

Antibiotics that act on membrane integrity also have varying effects on methanogens, as they do with eubacteria. Ionophores such as monensin, lasalocid, and gramicidin S are very effective inhibitors of methanogens. This inhibition is presumably the result of interference with Na^+ transport and thus with methanogenesis (Perski et al., 1982). Monensin and lasalocid inhibit both growth and methanogenesis (Dellinger and Ferry, 1984). However, this inhibition depends on the culture conditions, since they both stimulate methanogenesis at low Na^+ concentrations in vivo (Schönheit and Beimborn, 1986).

Motility

Motility in methanogens has been associated with the presence of flagella. However, little is known about their structure, attachment to the cell envelope, and the energetics of motility. Kalmokoff et al. (1988) found that the flagella of *Methanococcus voltae*, consisting of two protein subunits with molecular weights of 33,000 and 31,000, have a filament diameter of 13 nm, unlike those of eubacteria which generally consist of only one monomer. The basal structure is knob-like in appearance, as opposed to the multiple ring structure found in eubacteria. This may be due to the simpler structure of the methanococcal S-layer. It will be interesting to compare the basal structures of methanogens that have more

complex cell envelopes. The arrangement of flagella varies greatly among methanogen genera, as it does in eubacteria. *Methanococcus jannaschii* has lophotrichous flagella with two bundles of flagella at one pole arranged in a "corkscrew" fashion (Jones et al., 1983a). In contrast, *Methanogenium* species have peritrichous flagella (Romesser et al., 1979).

Chemotaxis in methanogens has been described in *Methanospirillum hungatei*, for which acetate is a chemoattractant (Migas et al., 1989). In addition, *Methanococcus voltae* responds to acetate, isoleucine, and leucine as attractants but not to histidine (Sment and Konisky, 1989). *M. voltae* has an absolute requirement for all these nutrients except histidine. Therefore, it is evident that some methanogens respond positively to higher nutrient concentrations. The advantage of this in certain habitats, such as marine marshes where substrate concentrations may be low, is self evident.

Applications

Methanogenic bacteria have numerous applications, especially in the degradation of wastes rich in organic matter to methane and CO_2 . Methane is the major component of natural gas, a clean fuel which is already in wide use. This topic has been reviewed extensively (Daniels, 1984; Hobson et al., 1981; van den Berg, 1984; Wodzinski et al., 1987), and only a few major points will be discussed here.

Because of the narrow substrate specificity of methanogens, pure cultures have limited usefulness in waste treatment. For most applications, consortia containing both methanogenic bacteria and heterotrophic bacteria capable of converting the complex organic materials common in waste materials to methanogenic substrates are used. The consortia are usually obtained from an inoculum of manure, sewage sludge, freshwater sediment, or some other natural source, and they are formed upon enrichment with the waste material of interest under methanogenic conditions. In this manner, consortia have been obtained for the degradation of a wide variety of wastes and other materials. Moreover, thermophilic consortia have been obtained by performing the enrichments at high temperatures.

For example, methanogenic consortia that degrade whey, a major by-product in milk and cheese production, have been described (Chartrain and Zeikus, 1986a, 1986b; Wildenauer and Winter, 1985; Zellner et al., 1987b; Zellner and Winter, 1987b). These consortia were composed of sugar- and protein-fermenting strains of *Lactobacillus*, *Eubacterium*, *Clostridium*, *Klebsiella*,

and *Leuconostoc*. Their fermentation products were then metabolized by acetogenic strains of *Desulfovibrio*, *Eubacterium*, and *Clostridium*. The acetate, H_2 , and formate formed were substrates in turn for the methanogens present, *Methanobacterium*, *Methanobrevibacter*, *Methanospirillum*, *Methanocorpusculum*, *Methanosaarcina*, and *Methanosaeta*. These complex consortia were capable of the nearly complete conversion of whey to methane and CO_2 within 5 days.

Another common application of methanogens is in the treatment of domestic sewage. Whether it be a simple cesspool or an advanced anaerobic digester, the methane produced from sewage can be collected and used to offset the cost of an otherwise obligatory process. In countries such as India and China, where the economic resources required for such digestors are not available, animal and human wastes are still used as a source of energy. Instead of advanced digestors, these countries have developed inexpensive small scale digestors for production of methane. In addition, the spent slurry can be used as a natural fertilizer. Obvious drawbacks of these digestors are their limited size and requirement for manual loading and emptying. The digestors are also limited to temperate climates since they must rely on the ambient temperature to eliminate the additional heating costs required to maintain an active biomass.

While consortia can be obtained for the conversion of many types of organic wastes to methane and CO_2 , the growth of these consortia is usually slow when compared to growth of those composed of aerobic microorganisms. This can cause problems since high waste input can result in loss of cell biomass, and thus waste decomposition is limited by the growth rate of the bacteria. Therefore, to increase efficiency, specialized bioreactors have been designed to retain the microbial population in the bioreactor while allowing for a high input of waste. In this way, the rate of waste decomposition is not limited by the growth rate of the bacteria. The five types of bioreactors commonly used have been reviewed by van den Berg (1984) and are described below:

1. The anaerobic contact reactor uses a sludge, which settles to the bottom and contacts the raw waste. Thus, the settling ability and mixing of the sludge with the waste are important in the efficiency of bioconversion. This bioreactor type works well for particulate wastes, which settle easily and are completely biodegradable.
2. The anaerobic filter reactor retains suspended bacteria and waste in a packing material or solid support where degradation occurs. It is advantageous for treatment of dilute soluble

wastes. However, it is easily plugged by suspended particulate waste.

3. The upflow anaerobic sludge bed reactor avoids plugging by reducing the volume of the packing material and using a gas collector to encourage settling of the sludge. High concentrations of microbial biomass are needed in addition to proper development of a granular sludge to promote settling.
4. The anaerobic fluidized or expanded bed reactors allow growth of biomass on inert particles, which settle and are suspended by a rapid flow of waste.
5. The downflow stationary fixed-film reactor avoids plugging of the anaerobic filter by forming an active biomass film. This reactor can accommodate a wide variety of wastes.

Another area of potential applications of methanogenic consortia is in degradation of xenobiotics (for reviews see Berry et al., 1987; Young, 1984). Especially important is the degradation of halogenated aromatic and aliphatic compounds, which are common pollutants. For instance, tetrachloroethylene is a common pollutant in ground waters due to improper disposal in landfills (Fatherpure and Boyd, 1988). In the presence of sewage sludge or pure cultures of methanogens, it is reductively dehalogenated to trichloroethylene. In contrast, tetrachloroethylene is not rapidly degraded under aerobic conditions. Likewise, low concentrations of chloroform, carbon tetrachloride, and 1,2-dichloroethane are almost completely oxidized to CO_2 by methanogenic consortia (Bouwer and McCarty, 1983). Haloaromatic compounds are also reductively dehalogenated by methanogenic consortia (Suffita et al., 1983). Thus, chlorinated phenols and chlorinated benzoates are converted to phenol and benzoate, respectively. Phenol may then be carboxylated to form benzoate (Knoll and Winter, 1989). Benzoate is then converted to methane and CO_2 , presumably by a reductive route via cyclohexane carboxylate.

Methanogens have also been implicated in anaerobic biocorrosion, which is a significant economic problem. By the process of cathodic depolarization, elemental iron is oxidized and protons in water are reduced to H_2 (Daniels et al., 1987). Methanogens accelerate this process by maintaining a very low partial pressure of H_2 . The mechanism is similar to that proposed for sulfate-reducing bacteria, which also consume H_2 . Protons from water combine with electrons from iron to form hydrogen, which is utilized by the hydrogenase enzyme.

Acknowledgements. The authors wish to thank Drs. Terry Miller, Josef Winter, and Tatjana

N. Zhilina for their critical reading of this manuscript.

The Order Methanomicrobiales

JEAN-LOUIS GARCIA, BERNARD OLLIVIER AND WILLIAM B. WHITMAN

Characteristics of Methanomicrobiales

Although their morphology is diverse, Methanomicrobiales can be distinguished from other methanogens by growth properties, cell wall and lipid composition, and rDNA sequence. All Methanomicrobiales can use $H_2 + CO_2$ as a substrate for methanogenesis, most species can utilize formate, and many species utilize alcohols (Table 1). They cannot use acetate and methylated C-1 compounds such as methanol, methylamines and methyl sulfides as substrates for methanogenesis, and this property distinguishes them from the *Methanosarcinales*. Notably, even though the Methanomicrobiales cannot use acetate as a substrate for methanogenesis, many species require acetate as a carbon source. The absence of hydroxyarchaeol in their lipids further distinguishes them from the *Methanosarcinales* (Koga et al., 1998). In addition, all of the Methanomicrobiales so far examined contain aminopentanetetrols, galactose and glycerol in their lipids, and aminopentanetetrols are unique to this taxon. The absence of pseudomurein further distinguishes the Methanomicrobiales from both the *Methanobacteriales* and *Methanopyrales*. Additional distinctive features are listed in Table 1. Based upon the phylogeny of the 16S rRNA genes as well as phenotypic and genotypic characteristics, the order Methanomicrobiales has been divided into three families and nine genera of hydrogenotrophic methanogens (Boone et al., 1993; Rouvière et al., 1992; Garcia et al., 2000; Tables 2 and 3). Twenty-four species have been described so far within this order (Tables 3 and 4). Because some species epithets are not in agreement with the International Nomenclature Code for Taxonomy, proposed changes for the original spelling are shown in brackets after the current name (Euzéby, 1997; Chong and Boone, 2004; Ferry and Boone, 2004).

Habitats of Methanomicrobiales

Like methanogens belonging to other orders, Methanomicrobiales inhabit diverse anaerobic habitats comprising marine and fresh water sediments, anaerobic digesters and the rumen. Although based upon classical microbiological characterizations, this conclusion has been well supported recently by a wide variety of molecular and immunological studies (Kudo et al., 1997; Munson et al., 1997; Grossköpf et al., 1998; Sekiguchi et al., 1999). Moreover, a hybridization probe specific to the three families belonging to this order has been designed and characterized for environmental and determinative microbiological studies (Raskin et al., 1994).

Eight of the 24 validly published species within the order Methanomicrobiales including species of the genera *Methanoculleus*, *Methanofollis*, and *Methanocorpusculum* have been isolated from anaerobic digestors or sewage sludge (Whitehead and Cotta, 1999). *Methanoculleus bourgense* was isolated from a tannery-byproducts enrichment-culture inoculated with sewage sludge (Ollivier et al., 1986), whereas *Methanoculleus palmolei* was obtained from a digester treating wastewater from a palm oil mill in Indonesia (Zellner et al., 1998). *Methanoculleus* sp. was shown to be involved in the syntrophic oxidation of acetate in digesters containing high concentrations of ammonium salts and volatile fatty acids (Schnurer et al., 1999). *Methanofollis liminatans* was isolated from the effluent of an anaerobic reactor treating industrial wastewater in Germany (Zellner et al., 1990). *Methanocorpusculum aggregans* originated from a municipal sewage sludge digester in France (Ollivier et al., 1985). Subsequently, a similar organism, *Methanocorpusculum parvum*, was enriched from an anaerobic sour whey digester inoculated with sewage sludge (Zellner et al., 1987). Thereafter, *Methanocorpusculum bavaricum* and *Methanocorpusculum sinense* were isolated from a wastewater pond of a sugar factory in Germany and from a pilot plant for treatment of distillery wastewater in China, respectively (Zellner et al., 1989b). Ecological

Table 1. Distinguishing features of the Methanomicrobiales.

Feature	<i>Methanomicrobiales</i>	<i>Methanococcales</i>	<i>Methanobacteriales</i>	<i>Methanosarcinales</i>	<i>Methanopyrales</i>
Morphology	Small rod, plate, irregular coccus, curved rod	Irregular coccus	Rod, short rod, coccus	Irregular coccus sometimes in aggregates, rod, flat polygon	Rod
Motility	+/-	+	-	-	+
Substrates ^a	H ₂ (for, alc)	H ₂ (for)	H ₂ (for, alc)	(me, H ₂ , ace)	H ₂
Temperature range, °C	0–60	18–94	20–97	2–70	84–110
Cell wall	Glycoprotein (sheath)	Protein	Pseudomurein	Glycoprotein (methanochondrotin, sheath)	Pseudomurein
Distinctive lipid components	Galactose, aminopentetetrols, glycerol	Serine	<i>myo</i> -Inositol, serine	Hydroxyarchaeol, <i>myo</i> -inositol, ethanolamine, glycerol	Galactose, mannose
Mol% G+C	38–61	30–33	26–61	36–54	60

Symbols: +, present in most or all taxa; -, present in a few or no taxa; and +/-, present in many but not all taxa.

Abbreviations: for, formate; alc, alcohols; me, methylamines; and ace, acetate.

^aSubstrates (in parentheses) are utilized by many but not all taxa.

Table 2. Some characteristics of the Methanomicrobiales families.

Family	Characteristics
<i>Methanomicrobiaceae</i>	Small rod, plate, or irregular coccus; substrates for methanogenesis are H ₂ + CO ₂ , frequently formate, and sometimes alcohols; Gram negative; motile or nonmotile; G+C content, 39–50mol%.
<i>Methanocorpusculaceae</i>	Small, irregular coccus, substrates for methanogenesis are H ₂ + CO ₂ , formate, and sometimes alcohols; Gram negative; motile or nonmotile; G+C content, 48–52mol%.
<i>Methanospirillaceae</i>	Curved rods; substrates for methanogenesis are H ₂ + CO ₂ , formate, and sometimes alcohols; Gram negative; motile; G+C content, 45–49mol%.

studies of a number of bioreactors have found varying contributions of the Methanomicrobiales to the methanogenic microflora. In a wood-fermenting bioreactor, *Methanomicrobium mobile* was the predominant methanogen, representing nearly 90% of all methanogens detectable by the immunological methods used (Macario et al., 1991). Such predominance of a single methanogen subpopulation has not been reported in other bioreactors so far and might be specific to wood-fermenting bioreactors. Nevertheless, in the 21 anaerobic sewage sludge digesters studied by Raskin et al. (1995), Methanomicrobiales together with *Methanosarcinales* represented the majority of the methanogens detected with oligonucleotide probes. In contrast, the Methanomicrobiales represented only a small fraction of the methanogens found in the granular consortia formed in an upflow anaerobic sludge blanket reactor (Visser et al., 1991).

Among the order Methanomicrobiales, six species belonging to genera *Methanolacinia*, *Methanogenium* and *Methanoculleus* were recovered from marine sediments and water. *Methanolacinia paynteri* was isolated from the edges of the mosquito control canals within mangrove swamps located in the Cayman Islands, British West Indies (Rivard et al., 1983). *Methanogenium cariaci*, *M. marisnigri* and *M. organophilum* were found in sediments from Cariaco Trench, the Black Sea, and near Venice (Italy), respectively (Romesser et al., 1979; Widdel, 1986; Widdel et al., 1988). The psychrophilic *Methanogenium frigidum* was isolated from the perennially cold, anoxic hypolimnion of a seawater-derived Antarctic meromictic lake (Franzmann et al., 1997), and the thermophilic *Methanoculleus thermophilicum* originated from sediments underlying the high temperature effluent channel of a nuclear power plant in Florida (Rivard and Smith, 1982). Moreover, examination of 16S rDNA libraries created with archaea-specific primers found sequences closely related to those of *Methanoculleus* and *Methanogenium* spp. from coastal salt-marsh sediment samples (Munson et al., 1997).

Members of the order Methanomicrobiales also were recovered from fresh water sediments. *Methanogenium frittonii* inhabits a freshwater lake in England (Harris et al., 1984). *Methanoculleus olentangyi* (Corder et al., 1983) and *Methanoculleus oldenburgensis* (Blotevogel et al., 1991) were isolated from river sediments in the United States and Germany, respectively. Finally, *Methanocorpusculum labreanum* was isolated from the surface sediments of Tar Pit Lake in Los Angeles (in the United States; Zhao et al., 1989). Likewise, small numbers of methanogens immunologically crossreactive with *Methanoculleus*

marisnigri and *Methanogenium cariaci* have been detected in other river and lake sediments (Caird et al., 1991).

Members of the order Methanomicrobiales have also been found (using in situ hybridization with a domain-specific oligonucleotide probe) on the surfaces of rice roots and in the surrounding paddy soil (Grossköpf et al., 1998). An irregular coccus phylogenetically related to *Methanoculleus marisnigri* was also isolated from a French ricefield soil (Joulian et al., 1998). Using molecular techniques, *Methanogenium*- and *Methanoculleus*-like organisms were shown to be also present in diverse ricefield soils in Japan (Kudo et al., 1997).

Subterrestrial ecosystems such as oil reservoirs and groundwaters are suitable habitats for Methanomicrobiales. *Methanoplanus petrolearius* and *Methanocalculus halotolerans* were isolated from an African offshore oil field (Ollivier et al., 1997) and from a French oil field (Ollivier et al., 1998), respectively. Isolates affiliated to *Methanoculleus* species have been recently obtained from Californian oil reservoirs (Orphan et al., 2000). Members of the genus *Methanomicrobium* have been identified in granitic groundwater (Pedersen, 1997). Other habitats for Methanomicrobiales include a swamp of drilling waste in Italy (*Methanoplanus limicola*; Wildgruber et al., 1982) and the mud of a small, moderately thermophilic solfatara pool at an altitude of 4,750 m in Chile (*Methanofollis tationis*; Zabel et al., 1984). Indirect immunofluorescence has also detected cells related to *Methanoculleus thermophilicum* in an alkaline Icelandic hot spring (Sonnehansen and Ahring, 1997).

Large quantities of methane are produced during the rumen fermentation. Species of the genus *Methanobrevibacter*, order *Methanobacteriales*, are the predominant methanogens in bovine and caprine rumina, whereas Methanomicrobiales are the predominant methanogens in the ovine rumen (Lin et al., 1997). *Methanomicrobium mobile* has also been found in high numbers in the bovine rumen and is probably a significant contributor to the total amount of methanogenesis (Paynter and Hungate, 1968; Jarvis et al., 2000). This conclusion is supported by molecular ecological studies that indicate Methanomicrobiales are the second most abundant methanogens in the bovine rumen and in model rumen systems, where they account for 12% of the total small subunit (SSU) rRNA in rumen fluid (Sharp et al., 1998). In addition, there is one report that *Methanogenium* spp. are the predominant methanogens in the gastrointestinal tracts of chickens and turkeys (Miller and Wolin, 1986).

Termites harbor symbiotic methanogens in their gut. Nucleotide sequences of PCR-amplified 16S ribosomal RNA genes from four termite species demonstrated that Methanomicrobiales species distinct from known species were present and constitute a unique phylogenetic group (Ohkuma et al., 1999).

Methanoarchaea ascribable to the genus *Methanogenium* also were recovered in low numbers from vegetables, meat, fish and cheese where they are thought to be chance contaminants (Brusa et al., 1998).

Although the Methanomicrobiales are generally free-living, some species are endosymbionts of anaerobic protozoa. Within the protozoa, they are associated with the hydrogenosome, suggesting that the symbiosis is based upon interspecies H_2 transfer from the protozoan to the methanogen (Berger and Lynn, 1992; Embley et al., 1992). For instance, *Methanoplanus endosymbiosus* is an endosymbiont of the sapropelic marine ciliate *Metopus contortus* (van Bruggen et al., 1986). Endosymbionts closely related to *Methanocorpusculum* and *Methanoplanus* spp. also have been identified within the anaerobic protozoa *Metopus*, *Trimyema* and *Pelomyxa*. These endosymbionts appear to be different from their free-living phylogenetic relatives, suggesting that some species may have adapted specifically to this lifestyle (Embley and Finlay, 1993; Finlay et al., 1993).

Isolation

ENRICHMENT MEDIA FOR GROWTH OF METHANOMICROBIALES Numerous types of media are appropriate for the growth of Methanomicrobiales. Representative media for isolating and culturing these microorganisms will be described in this section. All Methanomicrobiales are hydrogen-oxidizing organisms; they can grow on a mixture of molecular hydrogen (H_2) and carbon dioxide (CO_2 ; or bicarbonate [HCO_3^-]) according the following reaction:

$$\Delta G^{\circ'} = -135 \text{ kJ/mol of } CH_4$$

All except *Methanolacinia paynteri* can also use formate to produce methane (CH_4):

$$\Delta G^{\circ'} = -145 \text{ kJ/mol of } CH_4$$

Some species can also use secondary alcohols and CO_2 to produce methane and the organic acid or ketone:

The composition of growth medium will depend on the type of methanogen sought. Although most Methanomicrobiales will grow in one of these media described below, optimal growth may require 1) modification in the concentration of the mineral or organic components or 2) additional nutrients.

Standard Growth Medium 1

Values are per liter of medium.

K_2HPO_4	0.3 g
KH_2PO_4	0.3 g
$(NH_4)_2SO_4$	0.3 g
NaCl	0.6 g
$MgSO_4 \cdot 7H_2O$	0.13 g
$CaCl_2 \cdot 2H_2O$	8 mg
$FeSO_4 \cdot 7H_2O$	2 mg
Sodium acetate	0.5 g
Yeast extract	0.5 g
Trypticase	0.5 g
Cysteine-HCl	0.5 g
Trace minerals solution (see below)	10 ml
Resazurin	1 mg

This medium, adapted from that described by Balch et al. (1979), is recommended for isolation of species from freshwater sediments, sewage sludge or digesters.

The trace minerals solution (Balch et al., 1979) is composed of (per liter):

Nitrilotriacetic acid	1.5 g
$MgSO_4 \cdot 7H_2O$	3.0 g
$MnSO_4 \cdot 2H_2O$	0.5 g
NaCl	1.0 g
$FeSO_4 \cdot 7H_2O$	0.1 g
$CoSO_4$ or $CoCl_2$	0.1 g
$CaCl_2 \cdot 2H_2O$	0.1 g
$ZnSO_4$	0.1 g
$CuSO_4 \cdot 5H_2O$	0.01 g
$AlK(SO_4)_2$	0.01 g
H_3BO_3	0.01 g
$Na_2MoO_4 \cdot 2H_2O$	0.01 g

To prepare the trace minerals solution, dissolve the nitrilotriacetic acid in 800 ml of water and adjust the pH to 6.5 with KOH. Then dissolve the minerals in order, adjust the pH to 7.0, and bring the volume to 1 liter.

The vitamin solution (Balch et al., 1979) is composed of (per liter):

Biotin	2 mg
Folic acid	2 mg
Pyridoxine hydrochloride	10 mg
Thiamine hydrochloride	5 mg
Riboflavin	5 mg
Nicotinic acid	5 mg
DL-Calcium pantothenate	5 mg
Vitamin B_{12}	0.1 mg
<i>p</i> -Aminobenzoic acid	5 mg
Lipoic acid	5 mg

Standard Growth Medium 2

Values are per liter of medium:

K_2HPO_4	0.14 g
NH_4Cl	0.25 g
KCl	0.34 g

MgSO ₄ · 7H ₂ O	0.35 g
CaCl ₂ · 2H ₂ O	0.14 g
MgCl ₂ · 2H ₂ O	2.75 g
NaCl	18 g
Fe(NH ₄) ₂ (SO ₄) ₂ · 7H ₂ O	2 mg
Sodium acetate	1.0 g
Yeast extract	0.5 g
Trypticase	0.5 g
Cysteine-HCl	0.5 g
Trace minerals solution (see above)	10 ml
Vitamin solution (see above)	10 ml
Resazurin	1 mg

This medium, also adapted from that of Balch et al. (1979), is recommended for growth of marine species.

Medium 3 is for moderately halophilic Methanomicrobiales (from saline to hypersaline ecosystems). It contains the same components as Medium 1, but the saline (NaCl) concentration will vary depending on the (slight, moderate or extreme) salinity of the ecosystem studied. Among the species described so far, the upper NaCl limit for growth of any hydrogenotrophic methanogen belonging to the order Methanomicrobiales is 125 g/liter (Ollivier et al., 1998).

Medium 4 is for growth of species from the rumen. For enriching and isolating *Methanomicrobium* species from the rumen, clarified rumen fluid (rumen contents centrifuged at 25,000 × g for 15 min) is added to Medium 1. For *Methanomicrobium mobile*, the requirement for rumen fluid can be replaced by a complex mixture containing acetate, volatile fatty acids, amino acids, vitamins, and 7-mercaptoheptanoylthreonine phosphate (Kuhner et al., 1991; Tanner and Wolfe, 1988). Growth of *Methanoplanus endosymbiosus* is also dependent on rumen fluid, which can be replaced by the eluate of a rumen-derived anaerobic digester (Poirot et al., 1991). Para-cresol was identified as a growth-stimulatory component, and 50 nM of it supported the half-maximal growth.

All four media may be prepared anaerobically as follows. The pH of the medium is adjusted to 7.0 with 10 mM KOH. The medium is boiled under a stream of oxygen (O₂)-free nitrogen (N₂) gas and cooled to room temperature. It is then dispensed into Hungate tubes, serum bottles or flasks under a stream of N₂ + CO₂ (80:20, v/v) at atmospheric pressure. Vessels are autoclaved, and prior to culture inoculations, Na₂S · 9H₂O and NaHCO₃ are added from sterile anaerobic solutions to final concentrations of 0.04% and 0.2% (v/v), respectively. Sodium formate, added from a sterile anaerobic solution to a final concentration of 40 mM, or H₂ + CO₂ (80/20%; 2 bars) serves as energy source. Growth on alcohol (2-propanol, 1-propanol, ethanol, 2-butanol, 1-butanol or cyclopentanol) is tested at a final concentration of 20–30 mM (Widdel, 1986). Because gas is produced from formate and the alcohols,

care must be taken to avoid exceeding the pressure limit of the culture vessels during growth. Moreover, during growth on H₂ + CO₂, methanogens consume 5 moles of gas for every mole of CH₄ produced, and the vessel will quickly develop a negative pressure. A low internal pressure increases the possibility of contamination by air. In addition, the decrease in partial pressure of CO₂ renders the culture medium strongly alkaline, thus causing growth inhibition and cell lysis. To minimize these problems, the volume of the headspace should be at least five times the volume of the medium, and the culture vessels should be pressurized periodically throughout the growth period. The headspace also may be repressurized with H₂ + CO₂ to fully replenish the CO₂ consumed. For the thermophilic species, attention must also be given to the expansion of gas at high temperature.

Solid medium is prepared by the addition of 1.5–2% agar during the medium preparation. For the roll tube technique (Hungate, 1969), Hungate tubes are placed into a 45°C water bath after sterilization to prevent solidification of the molten agar. After inoculation, the tubes are rolled and rapidly cooled with an ice cube before incubation at the appropriate temperature. Petri plates may also be prepared in an anaerobic glove box and incubated in pressure cylinders (Balch et al., 1979) before removal from the chamber.

To measure the growth of methanogens, Hungate tubes with liquid cultures are directly inserted into a spectrophotometer, and the optical density at 580 nm is recorded.

ISOLATION AND CHARACTERIZATION For isolating Methanomicrobiales, enrichment cultures are initiated by inoculating the sample (10%) into serum bottles containing basal medium and H₂ + CO₂ or sodium formate as growth substrate. The inoculated serum bottles are incubated without shaking, except when H₂ is used as the energy source. Pure cultures are obtained by the repeated use of the Hungate roll tube technique (Hungate, 1969) using basal growth medium solidified with 1.5% (w/v) Noble agar (Difco). For thermophilic enrichments, the agar concentration is increased up to 2%. Characterization of the axenic strain should follow the guidelines of the International Committee on Systematic Bacteriology (ICSB) Subcommittee for the Taxonomy of Methanogens (Boone and Whitman, 1988). Growth rates at various pH values, temperatures and salt concentrations are determined in Hungate tubes of basal growth medium containing 40 mM sodium formate with a N₂ + CO₂ (80:20, v/v) atmosphere or in the absence of sodium formate with a H₂ + CO₂ (80:20, v/v) atmosphere. The pH is adjusted to the desired

value by injecting appropriate volumes of anaerobic sterile 10% (v/v) NaHCO_3 or Na_2CO_3 stock solutions. Both the initial and final pH must be recorded because the pH can change rapidly during growth. To determine the salt requirement for growth, NaCl is weighed directly in Hungate tubes, and the medium is subsequently dispensed as described above. The strain is subcultured at least once at each salt concentration prior to measurement of the growth rate.

To test substrate utilization, substrates are added from sterile stock solutions to the basal medium at a final concentration of 20 mM (ethanol, 1-propanol, 2-propanol, 1-butanol or isobutanol) or 40 mM (formate). The gas phase is $\text{N}_2 + \text{CO}_2$ (80:20, 200 kPa). Hydrogen oxidation is tested using $\text{H}_2 + \text{CO}_2$ (80:20, 200 kPa) in the gas phase. All experiments must be performed in duplicate. Also, susceptibility to lysis by detergents and hypotonic solutions, Gram staining, and motility should be determined. Phase contrast, fluorescence and electron microscopy are also used for phenotype characterization. Methane is quantified by gas chromatography to verify that it is the major catabolic product. If possible, it is also extremely desirable to determine the nutritional requirements for isolates obtained from complex medium.

The G+C content of DNA is determined by using high-performance liquid chromatography (HPLC), as described by Mesbah et al. (1989), after isolation and purification of the DNA by chromatography on hydroxyapatite. Nonmethylated lambda DNA (Sigma) is used as the standard. Sequencing of the gene for the 16S rRNA is also very desirable and may be necessary for final placement of an isolate with the Methanomicrobiales. A primer pair, designated "FARCH-9" (5'-CTGGTTGATCCTGCCAG-3') and "Rd1" (5'-AAGGAGGTGATCCAGCC-3'), is used to amplify the 16S rRNA gene from genomic DNA of Methanomicrobiales (Ollivier et al., 1998). The amplified product is purified (Andrews and Patel, 1996) and the sequence determined with an ABI automated DNA sequencer in conjunction with a Prism dideoxy terminator cycle sequencing kit and the protocol recommended by the manufacturer (Applied Biosystems Inc.). The primers used for sequencing are F2 (5'-CAGGATTAGATACCCTGGTAG-3'), R2 (5'-GTATTACCGCGGCTGCTG-3'), R4 (5'-CCGTCAATTCCTTTGAGTTT-3') and the two amplification primers FARCH9 and Rd1 described above. The 16S rRNA gene sequence is manually aligned with reference sequences of various members of the domain *Archaea* by using the alignment editor "ae2" (Maidak et al., 2000). Reference sequences are obtained from the Ribosomal Database Project (Maidak et al., 2000). Positions

of sequence and alignment uncertainty are omitted from the analysis. Pairwise evolutionary distances based on a number of unambiguous nucleotides are computed using the method of Jukes and Cantor (1969) and dendrograms are constructed from these distances using the neighbor-joining method. Both programs form part of the PHYLIP package (Felsenstein, 1993).

THE FAMILY METHANOMICROBIACEAE
Methanomicrobiaceae comprises seven genera with morphologies ranging from rods to highly irregular cocci or plane-shaped cells. The cell walls are proteinaceous and the lipids include both C_{20} and C_{40} isopranyl glycerol ethers. The sugars in glycolipids include glucose and galactose. The polar head groups contain aminopentanetetrals and glycerol. The mol% G+C for members of this family ranges from 38 to 62. Almost all strains can use formate. The use of secondary alcohols may be observed.

Methanomicrobium Genus *Methanomicrobium* is represented by a single mesophilic species, *Methanomicrobium mobile*.

Methanomicrobium mobile. These Gram-negative, slightly curved, short rods ($0.7 \times 1.5\text{--}2\text{ }\mu\text{m}$; Fig. 1) are sluggishly motile (with one polar flagellum) and subject to frequent lysis. Colonies are round, $1\text{ }\mu\text{m}$ in diameter, convex, smooth, translucent, with entire edges. Methane is produced from $\text{H}_2 + \text{CO}_2$ or from formate. Growth requires acetate and rumen fluid or a mixture of volatile fatty acids (VFA: isobutyrate, isovalerate,

Fig. 1. Electron micrograph of *Methanomicrobium mobile* showing the single polar flagellum. Bar = $1\text{ }\mu\text{m}$. (From Paynter and Hungate, 1968.)

and 2-methylbutyrate), amino acids (tryptophan or indole) and vitamins (pyridoxine, thiamine, biotin, vitamin B₁₂, and *p*-aminobenzoic acid), and 7-mercaptoheptanoylthreonine phosphate (component B). This latter compound can be replaced by 7-mercaptoheptanoate if the medium is also supplemented with an unidentified growth factor found in rumen fluid and extracts of *Methanobacterium thermoautotrophicum*. Optimum temperature and pH for growth are 40°C (range 30–45°C) and 6.1–6.9 (range 5.9–7.7), respectively. This organism was isolated from rumen fluid. Its DNA G+C content is 49 mol%. Its GenBank 16S rRNA sequence accession number is M59142. It is the type (and only) species of this genus; the type strain is DSM 1539 (≡ ATCC 35094). Refer to Paynter and Hungate (1968); Tanner and Wolfe (1988); and Kuhner et al. (1991).

Methanolacinia

Genus *Methanolacinia* has only one representative, *Methanolacinia paynteri* (formerly *Methanomicrobium paynteri*).

Methanolacinia paynteri. These Gram-negative, pleomorphic, short and highly irregular coccoid to lobe-shaped cells (about 1.5–2.0 µm in diameter; Fig. 2) usually occur singly and are flagellated but only weakly motile or nonmotile. Cells lyse in detergents. The cell envelope consists of a hexagonally arranged S-layer with a glycoprotein of Mr 155,000 and a lattice constant of 15.3 nm (Fig. 3). Colonies are circular, 1–2 µm in diameter, off-white, with entire edges. Methane is produced from H₂ + CO₂, 2-propanol + CO₂, 2-butanol + CO₂, or cyclopentanol + CO₂. No growth or methane production is detected on formate, acetate, methylamines, ethanol, 1-propanol, 1-butanol, and cyclohexanol. Growth requires acetate. Polar lipids consist of di- and tetraether lipids and include phosphatidyl glycerol diether (PG), phosphatidyltrimethylaminopentanol diether (PPTAD), diglycosyldiether, presumptive phosphatidylaminopentanol diether (PPAD) and the corresponding phosphoglycolipid ethers. Putrescine and spermidine are the only polyamines. Optimum growth temperature and pH are 40°C (range 20–45°C) and 7.0 (range 6.6–7.3), respectively. Growth is optimal in 0.15 M NaCl (range 0–0.8 M). Minimum generation time is 4.8 h. The G+C content of DNA is 44 mol% (by buoyant density; BD) and 38 mol% (by thermal denaturation; T_m). This organism was isolated from marine sediments. *Methanolacinia paynteri* is the type species of the genus; its type strain is G-2000 (≡ DSM 2545 or ATCC 33997). Refer to Rivard et al. (1983) and Zellner et al. (1989a).

Fig. 2. Electron photomicrograph of a group of typical cells of *Methanolacinia paynteri*. (From Rivard et al., 1983.)

Fig. 3. Electron microphotograph of a freeze-etched preparation of *Methanolacinia paynteri*; bar = 0.1 µm. (From Zellner et al., 1989a.)

Methanogenium

Genus *Methanogenium* comprises four species. These highly irregular cocci are Gram negative. Although motility has not been observed, flagella are sometimes present. The cell wall is composed of regular glycoprotein subunits. Cells require growth factors, use formate, and are readily lysed in dilute detergents. The G+C content varies from 47 to 52 mol%. Two species were shown to use both CO₂ and secondary alcohols to form methane. *Methanogenium frittonii* is a thermophilic species (optimum temperature for growth, 57°C), whereas *M. frigidum* is psychrophilic (optimum temperature for growth, 15°C).

Methanogenium cariaci (*cariacense*). Though motility has never been observed, these highly irregular cocci (1.3–2.6 µm in diameter) have peritrichous thin flagella up to 18 µm long and long thin pili about 4 nm in diameter. Though the cell is Gram negative, its cell wall lacks an outer

membrane and has a periodic surface pattern consisting of structural units about 14 nm in diameter; these particles seem to be composed of several subunits (Fig. 4). The cells are sensitive and 1% SDS. Colonies are circular, umbonate, greenish yellow with entire edges, shiny, 0.5 μm in diameter after two weeks of incubation, and 4 μm after 14 weeks. Methane is produced from $\text{H}_2 + \text{CO}_2$ or from formate. Growth requires yeast extract and acetate. Optimum temperature and pH for growth are 20–25°C (range 15–35°C) and 6.8–7.3 (range 6–7.6), respectively. Isolated from marine sediments, these organisms grow optimally in 0.54 M NaCl (range 0.2–0.8 M). The G+C content of DNA is 52 mol% (BD). The GenBank 16S rRNA sequence accession number is M59130. *Methanogenium cariaci* is the type species of its genus; the type strain is JR1 (\equiv DSM 1497, ATCC 35093 or OCM 155). Refer to Romesser et al. (1979).

Methanogenium frigidum. These Gram-negative, irregular cocci (1.2–2.5 μm in diameter) are nonmotile and sensitive to 0.1% of SDS; cells occur singly without flagella or pili. The cell wall has an S-layer exterior to the plasma membrane and a fibrous coat exterior to the S-layer. Colonies are circular, smooth, green-yellow with entire edges. Methane is produced from $\text{H}_2 + \text{CO}_2$ or from formate. No growth or methane production is detected on acetate, trimethylamine or methanol. Growth requires acetate and is stimulated by yeast extract and peptones. Sulfide can serve as a sole sulfur source, and ammonia serves as a sole nitrogen source. An obligate psychrophile, this species grows optimally at 15°C (range 0–17°C). Optimal growth occurs at pH 7.5–7.9 (range 6.3–8.0) and in 0.35–0.6 M NaCl (range >0.1–<0.85 M). The minimum generation time is 2.9 days. The G+C content of DNA is 52 mol%; the GenBank 16S rRNA sequence accession number is AF009219. This

Fig. 4. Electron microphotograph of a freeze-etched preparation of (A) *Methanogenium cariaci* and (B) *Methanogenium marisnigri* showing particulate nature of the cell walls. (From Romesser et al., 1979.)

species was isolated from the perennially cold, anoxic hypolimnion of Ace Lake in Antarctica. The type strain is Ace-2T (\equiv SMCC 459W or OCM 469). Refer to Franzmann et al. (1997).

Methanogenium frittonii. These irregular cocci (1–2.5 μm in diameter) are nonmotile, fimbriated, and occur singly or in pairs. Cells are surrounded by a protein envelope (20 nm thick) and are disrupted by pronase and trypsin digestion, glass-distilled water and 1% SDS. Colonies (1–2 μm in diameter) are circular, convex, shiny, dark yellow with entire edges. Methane is produced from $\text{H}_2 + \text{CO}_2$ or from formate. Growth is stimulated by yeast extract, tryptone, and casamino acids. Optimum temperature for growth is 57°C (range 26–62°C); optimum pH is 7.0–7.5 (range 6.0–8.25). NaCl is not required and is inhibitory above 2%. The G+C content of DNA is 49.2 mol% (BD). This organism was isolated from lake sediment. The type strain is FR-4 (\equiv DSM 2832 or OCM 200). Refer to Harris et al. (1984).

Methanogenium organophilum (*organophilum*). These irregular cocci (0.5–1.5 μm in diameter) are nonmotile and subject to detergent lysis, e.g., by 0.01% or less SDS. Colonies are smooth and yellowish. Methane is produced from $\text{H}_2 + \text{CO}_2$, formate, 2-propanol + CO_2 , 2-butanol + CO_2 , ethanol + CO_2 and 1-propanol + CO_2 . No growth or methane production is detected on acetate or methanol. Secondary alcohols are oxidized to ketones, and primary alcohols are oxidized to monocarboxylic acids. Acetate has to be added as a carbon source for growth on substrates other than ethanol. 4-Aminobenzoate, biotin, vitamin B₁₂, and tungstate are required for growth. Optimum temperature for growth is 30–35°C (maximum 39°C); optimum pH is 6.4–7.3; growth is optimal with 20 g/liter of NaCl and 3 g/liter of MgCl₂. Minimum generation time is 6 h on H_2 and 11 h on 2-propanol + CO_2 . The G+C content of DNA is 46.7 mol% (Tm); the GenBank 16S rRNA sequence accession number is M59131. This species was isolated from marine mud. The type strain is CV (\equiv DSM 3596 or OCM 72). Refer to Widdel et al. (1988).

Methanoculleus

The genus *Methanoculleus* (Maestrojuan et al., 1990) consists of five mesophilic species (including one subject synonym) and one thermophilic species of Gram-negative, highly irregular cocci. Motility has not been observed, although flagella are present in some species. Formate is used by five species. The G+C content range is between 49 and 62 mol%. The type species is *Methanoculleus bourgense*. However, DNA hybridization and rRNA sequence similarity suggest that this

species may be a subjective synonym of *Methanoculleus olentangyi* (Rouvière et al., 1992; Boone et al., 1993). If this proposal is borne out by further investigations, strains of *M. bourgensis* will be reclassified as *M. olentangyi* because it is the senior synonym, and the genus *Methanoculleus* will become invalid without action by the ICSB.

Methanoculleus bourgensis (*bourgensis*). These Gram-negative, irregular cocci (1–2 µm in diameter) are nonmotile and subject to lysis by 0.02% SDS. Colonies are circular, convex and white to yellowish. Methane is produced from $H_2 + CO_2$ or from formate. Acetate is required for growth. Growth is stimulated by yeast extract and trypticase. Optimum temperature for growth is 35–40°C (range 30–50°C); optimum pH is 6.7 (range 5.5–8.0); and growth is optimal with 10 g/liter of NaCl (range 0–20 g/liter). The G+C content of DNA is 59 mol% (BD). The GenBank 16S rRNA sequence accession number is AF095269. The organism was isolated from a tannery-byproduct enrichment-culture inoculated with sewage sludge. It is the type species of genus *Methanoculleus*; the type strain is MS2 (≡ DSM 3045, ATCC 43281 or OCM 15). Refer to Ollivier et al. (1986) and Maestrojuan et al. (1990).

Methanoculleus marisnigri (*marisnigri*). These Gram-negative, irregular cocci (1.3 µm in diameter) have peritrichous flagella (13 µm long). The cell wall has a periodic surface pattern of 14 nm in diameter. Cells are sensitive to lysis by 1% SDS. Colonies are circular, convex, yellow, shiny and have entire edges. Methane is produced from $H_2 + CO_2$, formate, 2-propanol + CO_2 , or 2-butanol + CO_2 . No growth or methane production is detected on acetate or methanol. Growth requires trypticase. Optimum temperature for growth is 20–25°C (range 15–45°C); optimum pH is 6.2–6.6 (range 5.7–7.6); growth is optimal in 0.1 M NaCl (range 0–0.7 M). The G+C content of DNA is 61.2 mol% (BD); the GenBank 16S rRNA sequence accession number is M59134. This organism was isolated from marine sediments. Its type strain is JR1 (≡ DSM 1498 or ATCC 35101). Refer to Romesser et al. (1979) and Maestrojuan et al. (1990).

Methanoculleus oldenburgensis. These irregular cocci (0.5–1.5 µm in diameter) are nonmotile, fimbriated single cells, seldom in pairs, and highly sensitive to detergents, e.g., 0.01% Triton X-100 or SDS. The cell envelope consists of a protein S-layer. The cells contain putrescine, sym-homospermidine and spermine as typical polyamines. Methane is produced from $H_2 + CO_2$ or from formate. Growth requires acetate. Optimum temperature for growth is 45°C (range 25–50°C); optimum pH is 7.5–8.0 (range 6.5–8.5); NaCl is not required and inhibitory at

Fig. 5. (a) Electron micrographs of a thin section of a cell of *Methanoculleus palmolei*; bar = 0.1 µm. (b) Electron micrograph of a freeze-etched preparation of *Methanoculleus palmolei* showing the hexagonal arrangement of the S-layer glycoproteins and a piece of a flagellum (marked F); bar = 0.1 µm. (From Zellner et al., 1998.)

levels exceeding 1.5%. The G+C content of DNA is 48.6 ± 1 mol% (Tm). This organism was isolated from river sediments. Its type strain is CB-1 (≡ DSM 6216). Refer to Blotvogel et al. (1991).

Methanoculleus olentangyi (*olentangyense*). These irregular cocci (1–4.5 µm in diameter) are nonmotile and subject to lysis by 0.001% SDS and distilled water. Colonies are circular, convex, mucoid, shiny and yellow. Methane is produced from $H_2 + CO_2$ or from formate. No growth or methane production is detected on methanol and methylamines. Growth requires acetate. Optimum temperature for growth is 37°C (range 30–45°C); growth is optimal in 1% NaCl (range 0–3%). The G+C content of DNA is 54.4 mol% (BD). The GenBank 16S rRNA sequence accession number is AF095270. This organism was isolated from river sediments. Its type strain is RC/ER (= DSM 2772, ATCC 35293 or OCM 52). It is a subjective synonym of *M. bourgensis*. Refer to Corder et al. (1983) and Maestrojuan et al. (1990).

Methanoculleus palmolei. The motility of these Gram-negative, highly irregular cocci (1.25–2 µm in diameter), though flagellated, has not been observed. Cell walls have S-layers of hexagonally arranged glycoprotein subunits (Mr 120,000; Fig. 5). The cells contain putrescine, sym-homospermidine and spermine as typical polyamines. Methane is produced from $H_2 + CO_2$, formate, 2-propanol + CO_2 , 2-butanol + CO_2 , or cyclopentanol + CO_2 . No growth or methane production is detected on acetate, methanol, ethanol, 1-propanol, 2-pentanol + CO_2 , 2,3-butanediol, dimethylamine and lactate. Growth requires acetate and is stimulated by potassium and tungstate ions. Optimum temperature for growth is 40°C

Fig. 6. Platinum-iridium shadowed cells of *Methanoculleus thermophilicus* (a) strain Ratisboa, (b) DSM 2373 and (c) strain Los Angeles. (From Zabel et al., 1985.)

(range 22–50°C); optimum pH is 6.9–7.5 (range 6.5–8.0); minimum generation time is 13.5 h. The G+C content of DNA is 59–59.5 mol% (Tm, HPLC); the GenBank 16S rRNA sequence accession number is Y16382. This organism was isolated from a digester treating wastewater of a palm oil mill in Indonesia. The type strain is INSLUZ T (\equiv DSM 4273T). Refer to Zellner et al. (1998).

Methanoculleus thermophilicus (*thermophilicus*). These Gram-negative, irregular cocci to coccobacilli (0.7–1.8 μm in diameter; Fig. 6) occur singly or in pairs and have occasional internal membrane components. Cell envelope is composed of protein subunits and contains a glycoprotein (130 kD). One flagellum and pili are present; motility is not observed or weak. Colonies are circular, beige, with entire edges. Methane is produced from $\text{H}_2 + \text{CO}_2$ or from formate. No growth or methane production is detected on acetate, methanol, ethanol, propionate, pyruvate, dimethylamine and trimethylamine. Growth requires acetate, a trace vitamin solution and trypticase (or peptone or yeast extract). Optimum temperature for growth is 55–60°C; optimum pH is 6.7–7.2; optimum NaCl concentration is 0–0.3 M. The G+C content of DNA is 56–60 mol% (Tm); the GenBank 16S rRNA sequence accession number is M59129. This organism was isolated from digesters and marine sediments. The type strain is CR-1 (\equiv DSM 2373, ATCC 33837 or OCM 174). Refer to Rivard and Smith (1982), Zabel et al. (1985), and Maestrojuan et al. (1990).

Methanoplanus

The genus *Methanoplanus* comprises three species of plane-shaped organisms. The cell walls contain at least one major glycoprotein. Formate is used for methanogenesis. One species is an

endosymbiont of marine ciliates and is found in close association with microbodies that are thought to provide H_2 to the methanogen. The methanogen functions as an electron sink in the oxidation steps of the carbon flow in the ciliates. This symbiotic relationship is thought to be responsible for a total conversion of metabolites to CO_2 and CH_4 in marine sediments. The G+C range of the genus is 39 to 50 mol%.

Methanoplanus endosymbiosus. These Gram-negative, irregular discs with a diameter of 1.6–3.4 μm occur singly and are nonmotile despite the presence of peritrichous flagella or pili. The cell envelope shows a regular hexagonal surface pattern and consists of proteins. Cells are lysed by 0.001% SDS or 0.01% Triton X-100 in 2% NaCl. Colonies are circular with entire margins, shiny, convex and whitish yellow. Methane is produced from $\text{H}_2 + \text{CO}_2$ or from formate. No growth or methane production is detected on acetate, methanol or methylamine. Tungsten (0.1 mM) is required for growth, which is stimulated by yeast extract, tryptone or rumen fluid. *p*-Cresol replaces the requirement for rumen fluid. Optimum temperature for growth is 32°C (range 16–36°C); optimum pH is 6.8–7.3 (range 6.3–7.8); and optimum NaCl concentration is 0.25 M (range 0–0.75M). Minimum generation time is 7–12 h. The G+C content of DNA is 38.7 mol% (Tm). The GenBank 16S rRNA sequence accession number is Z29435. This organism was found as an endosymbiont in the marine ciliate *Metopus contortus*. The type strain is DSM 3599. Refer to Van Bruggen et al. (1986) and Poirot et al. (1991).

Methanoplanus limicola. These Gram-negative, angular, crystal-like plates with sharp edges (0.07–0.3 μm thick, 1.6–2.8 μm long, 1.5 μm wide) occur singly (Fig. 7). The cells are sometimes branched, without septa, and contain electron-dense round inclusions. The cell envelope shows a hexagonal surface pattern and contains a dominant glycoprotein. A polar tuft of flagella can be seen, and the cells are weakly motile. Cells are lysed by 2% SDS. Colonies on polysilicate are round, smooth, bright, ochre-colored, and flat (about 2 μm in diameter). Cells are resistant to vancomycin, penicillin, kanamycin and tetracycline. Methane is produced from $\text{H}_2 + \text{CO}_2$ or from formate. No growth or methane production is detected on acetate, methanol or methylamines. Acetate (0.1%) is required for growth, which is stimulated by yeast extract (or peptones and vitamins). Optimum temperature for growth is 40°C (range 17–41°C); optimum pH is 7 (range 6.5–7.5); and optimum NaCl concentration is 1% (range 0.4–5.4%). The G+C content of DNA is 47.5 mol% (Tm). This organism was isolated from a swamp of drilling waste in Italy. Its GenBank 16S rRNA sequence

Fig. 7. Light and electron micrographs of *Methanoplanus limicola*. (a) Phase contrast of exponentially growing cells; arrows indicate bacteria appearing in profile; (b) platinum shadowed; (c, d) thin sections. The bars are of indicated size in μm . (From Wildgruber et al., 1982.)

accession number is M59143. *Methanoplanus limicola* is the type species of its genus. The type strain is M3 (\equiv DSM 2279, ATCC 35062 or OCM 101). Refer to Wildgruber et al. (1982).

Methanoplanus petrolearius. These irregular disc-shaped cells (1–3 μm in diameter) occur singly or in pairs and are nonmotile. Colonies are round (1–2 μm in diameter). Methane is produced from $\text{H}_2 + \text{CO}_2$, formate or 2-propanol + CO_2 . No growth or methane production is detected on acetate, methanol, trimethylamine, lactate, glucose, 1-propanol, 1-butanol, or isobutanol. Acetate is required for growth, which is stimulated by yeast extract. Optimum temperature for growth is 37°C (range >25–<45°C); optimum pH is 7 (range 5.3–8.4); optimum NaCl concentration is 1–3% (range 0–5%). Minimum generation time is 10 h. The G+C content of DNA is 50 mol% (HPLC). This organism was isolated from an oil-producing well. The GenBank 16S rRNA sequence accession number is U76631. The type strain is SEBR 4847T (\equiv DSM 11571 or OCM 486). Refer to Ollivier et al. (1997).

Methanofollis

This genus has been proposed to reclassify *Methanogenium tationis* and *M. liminatans*. These two species use formate and have a G+C content of 54–61 mol%.

Fig. 8. Electron photomicrographs of platinum-iridium shadowed cells of *Methanofollis tationis*: (a) whole cells with peritrichous flagellation; (b) cell surface showing the hexagonal subunit structure; both bars = 0.5 μm . (From Zabel et al., 1984.)

Methanofollis liminatans. These irregular cocci (1.5 μm in diameter) are flagellated and motile. The cell envelope consists of hexagonally arranged glycoproteins. Cells grow in a synthetic, acetate-containing low-salt medium with substrates $\text{H}_2 + \text{CO}_2$, formate, 2-propanol + CO_2 , 2-butanol + CO_2 , or cyclopentanol + CO_2 . No growth or methane production occurs with acetate, methanol, ethanol or dimethylamine. Tungstate (1–2 mM) stimulates growth. Optimum temperature for growth is 40°C (range >25–<45°C); optimum pH is 7; optimum NaCl concentration is 0–0.6 M (range 0–<0.8 M). Minimum generation time is 7.5–8.5 h. The G+C content of DNA is 59.3 mol% (Tm) and 60.5 mol% (HPLC). This organism was isolated from effluent of a digester for the treatment of industrial waste water. The GenBank 16S rRNA sequence accession number is AF095271. The type strain is GKZPZ (\equiv DSM 4140). Refer to Zellner et al. (1990) and Zellner et al. (1999).

Methanofollis tationis (*tatioense*). These Gram-negative, regular or highly irregular cells, depending on the salt concentration in the medium, approximate 3 μm in diameter (Fig. 8), have peritrichous flagella, and lyse in 1% SDS. The cell envelope is composed of hexagonal protein subunits, which seem to contain a glycoprotein. The cytoplasm has numerous polyphosphate inclusions. Methane is produced from $\text{H}_2 + \text{CO}_2$ or from formate. No growth or methane production is detected on acetate, methanol, ethanol, ethyl acetate, dimethylamine or trimethylamine. Yeast extract, peptone and acetate are required for optimal growth. Yeast extract and peptone can partially be replaced by a heavy metal solution. Optimum temperature for

growth is 37–40°C (range 25–45°C); optimum pH is 7 (range 6.3–8.8); optimum NaCl concentration is 0.8–1.2% (range 0–7%). Minimum generation time is 12 h at 40°C. The G+C content of DNA is 54 mol% (Tm). This organism was isolated from solfataric pools at an altitude of 4,750 m. The GenBank 16S rRNA sequence accession number is AF095272. *Methanofollis tationis* is the type species of this genus. The type strain is DSM 2702. Refer to Zabel et al. (1984) and Zellner et al. (1999).

The Family Methanocorpusculaceae

Methanocorpusculum

The family *Methanocorpusculaceae* (Zellner et al., 1989b) comprises one genus, *Methanocorpusculum*, and five mesophilic species (including one subjective synonym) of irregular cocci. They all use $H_2 + CO_2$ and formate, and some species can use 2-propanol + CO_2 . The type species is *Methanocorpusculum parvum* (Zellner et al., 1987). However, *Methanocorpusculum aggregans* (formerly *Methanogenium aggregans*) was isolated prior to *M. parvum* and has been shown to be closely related, with about 70% DNA reassociation (Ollivier et al., 1985; Xun et al., 1989). The high level of DNA reassociation suggests that *M. parvum* and *M. aggregans* may be subjective synonyms (Boone et al., 1993). If further investigations support this conclusion, *M. aggregans* would have precedence over *M. parvum*, which would then have to be reclassified as *M. aggregans* subspecies *parvum*. This reclassification would then invalidate the genus *Methanocorpusculum* as well as the family *Methanocorpusculaceae*. *Methanocorpusculum parvum* is of special interest because it requires high levels of tungstate for growth (Zellner et al., 1987). It is also the first hydrogenotrophic methanogen found to possess cytochromes. Presumably, these cytochromes are involved in the oxidation of 2-propanol. The mol% G+C of this genus ranges from 48 to 52.

Methanocorpusculum aggregans. These Gram-negative, irregular cocci (0.5–2 µm in diameter) occur singly or in aggregates (Fig. 9) and are nonmotile and sensitive to 0.03% SDS. Colonies (3–4 µm in diameter) are round, convex, and white to yellow. Methane is produced from $H_2 + CO_2$ or from formate. No growth or methane production is detected on acetate, methanol or methylamines. Acetate and yeast extract or trypticase are required for growth. Optimum temperature for growth is 35°C (range 27–38°C); optimum pH is 6.6 (range 6.2–7.5); optimum NaCl concentration is 0% (range 0–2%). Mini-

Fig. 9. (a) Phase-contrast photomicrograph of aggregates of *Methanocorpusculum aggregans*; bar = 10 µm; (b) thin-section electron photomicrograph of an individual cell of *Methanocorpusculum aggregans*; bar = 0.5 µm. (From Ollivier et al., 1985.)

mum generation time is 8 h. The G+C content of DNA is 52 mol% (BD). This organism was isolated from a sewage sludge digester. The type strain is Mst (=DSM 3027 or OCM 21). It is possibly a subjective synonym of *M. parvum*. Refer to Ollivier et al. (1985) and Xun et al. (1989).

Methanocorpusculum bavaricum. These Gram-negative, small, irregular cocci (<1 µm in diameter) occur singly and are flagellated and weakly motile. The cell envelope consists of a hexagonally arranged S-layer with a center-to-center spacing of the glycoprotein subunits of 16 nm (Fig. 10). Methane is produced from $H_2 +$

Fig. 10. Electron micrograph of a freeze-etched preparation of (1) *Methanocorpusculum parvum*; (2) *M. sinense*; (3) *M. bavaricum*; bar = 0.1 μm . (From Zellner et al., 1989b.)

CO_2 , formate, 2-propanol or 2-butanol. No growth or methane production is detected on acetate, methanol, methylamines, ethanol, 1-propanol, 1-butanol or cyclohexanol. Rumen fluid is required for growth, which is stimulated by tungstate (1 mM). Optimum temperature for growth is 37°C (range 15–45°C); optimum pH is 7. The G+C content of DNA is 47.7 mol% (Tm), 51% (HPLC). This organism was isolated from anaerobic sediment of a sugar factory's wastewater treatment pond. Its GenBank 16S rRNA sequence accession number is AF042197. The type strain is SZSXXZ (\equiv DSM 4179 or OCM 127). Refer to Zellner et al. (1989b).

Methanocorpusculum labreanum. These Gram-negative, irregular cocci are 0.4–2 μm in diameter. The degree of irregularity is dependent on the physiological state of the cells and on the ionic strength of the medium. The cells are non-motile, sensitive to 0.02% SDS, and have a protein cell wall. Colonies are circular (0.5 μm in diameter), clear, and convex with entire edges. Methane is produced from $\text{H}_2 + \text{CO}_2$ or formate. No growth or methane production is detected on acetate, propionate, methanol, trimethylamine or ethanol. Trypticase, peptone or yeast extract is required for growth, which is stimulated by acetate. Optimum temperature for growth is 37°C (range 25–40°C); optimum pH is 7 (range 6.5–7.5); optimum NaCl concentration is 0–1.5% (range 0–<3%). The G+C content of DNA is 50 mol% (BD). This organism was isolated from surface sediments of Tar Pit Lake in Los Angeles, California. The GenBank 16S rRNA sequence accession number is AF095267. The type strain is ZT (\equiv DSM 4855, ATCC 43576, or OCM 1). Refer to Zhao et al. (1989).

Methanocorpusculum parvum. These Gram-negative, irregular cocci (= 1 μm in diameter) occur singly or in pairs. Each cell has one flagellum and is weakly motile. The cell envelope consists of hexagonally arranged protein sub-

structures (Fig. 10). Complete lysis occurs with 1% SDS. Methane is produced from $\text{H}_2 + \text{CO}_2$, formate or 2-propanol + CO_2 . No growth or methane production is detected on acetate, propionate, methanol, methylamines, ethanol, pyruvate, lactate, butyrate, 1-butanol, 2-pentanol, formaldehyde, L-alanine, L-lysine or L-leucine. Yeast extract, acetate and tungsten (1 mM) are required for growth, which is stimulated by clarified rumen fluid. Optimum temperature for growth is 37°C (range 20–40°C); optimum pH is 6.8–7.5; optimum NaCl concentration is 0% (range 0–5%). Minimum generation time is 8 h. The G+C content of DNA is 48.5 mol% (Tm).

This organism was isolated from an anaerobic sour whey digester inoculated with sewage sludge. The GenBank 16S rRNA sequence accession number is M59147.

Methanocorpusculum parvum is the type species of this genus and possibly a subjective synonym of *M. aggregans*. The type strain is XII (\equiv DSM 3823, ATCC 43721 or OCM 63). Refer to Zellner et al. (1987).

Methanocorpusculum sinense. These Gram-negative organisms occur singly as flagellated, weakly motile, small, irregular cocci (<1 μm in diameter). The cell envelope consists of a hexagonally arranged S-layer with a center-to-center 15.8-nm spacing of the glycoprotein subunits (Fig. 10). Colonies are circular, convex with entire edges. Methane is produced from $\text{H}_2 + \text{CO}_2$ or from formate. No growth or methane production is detected on acetate, methanol, methylamines, ethanol, 1-propanol, 2-propanol, 1-butanol, 2-butanol or cyclohexanol. Clarified rumen fluid is required for growth. Optimum temperature for growth is 30°C (range 15–45°C); optimum pH is 7. The G+C content of DNA is 52 mol% (Tm) and 50 mol% (HPLC). This organism was isolated from an anaerobic biogas plant treating distillery wastewater. The GenBank 16S rRNA sequence accession number is AF095268. The type strain is CHINAZ (\equiv DSM 4274 or OCM 128). Refer to Zellner et al. (1989b).

The Family Methanospirillaceae

Methanospirillum

Based upon its unique morphology and low 16S rRNA sequence similarity to the other Methanomicrobiales, the family *Methanospirillaceae* was created to include the single genus *Methanospirillum* (Boone et al., 1993). Members of the genus are mesophilic and have been reported from a wide range of habitats. However, only one species, *Methanospirillum hungatei*, has been described so far.

Fig. 11. Phase-contrast photomicrograph of (a) long, wavy filament and (b) individual cells of *Methanospirillum hungatei*. Both bars = 10 µm. (From Mah and Smith, 1981.)

Methanospirillum hungatei (*hungateii*). These Gram-negative, curved rods (7.4 µm × 0.5 µm) form filaments from 15 µm often to several hundred µm in length (Fig. 11). Possessing polar, tufted flagella and sheaths, cells exhibit weak motility and progressive movement. The cell envelope and sheath have been extensively studied (see below). Cells are striated on the surface and resistant to lysozyme. Colonies are circular, <3 µm in diameter, light yellow, convex with lobate margins, uniquely striated when observed under low-power magnification. The type species forms methane from H₂ + CO₂ or from formate, and some strains (GP1 and SK) are able to use 2-propanol + CO₂ or 2-butanol + CO₂ (Widdel, 1986; Widdel et al., 1988). No growth or methane production is detected on acetate, methanol, ethanol, pyruvate or benzoate.

Methanospirillum hungatei has a positive chemotactic response to acetate (Migas et al., 1989). Yeast extract and trypticase are stimulatory for growth. Optimum temperature for growth is 30–37°C; optimum pH is 6.6–7.4. The G+C content is 45–49 mol% (BD). This hydrogenotrophic methanogen shows a high affinity for hydrogen and is often utilized for isolation of syntrophic bacteria in place of sulfate-reducing bacteria when sulfate is not available in the culture medium. This organism was isolated from various anaerobic environments. Its GenBank 16S rRNA sequence accession number is M60880. It is the type species of genus *Methanospirillum*. Its type strain is JF1 (≡ DSM 864, ATCC 27890 or OCM 16). Refer to Ferry et al. (1974), Patel et al. (1976), Ferry and Wolfe (1977), and Widdel et al. (1988).

Genus *insertae sedis*

Methanocalculus

It is a newly described genus that encompasses two irregular cocci, *Methanocalculus halotolerans*, an isolate from an offshore oil well, and *M. pumilus*, isolated from a waste-disposal site. *Methanocalculus halotolerans* is a hydrogenotrophic halotolerant methanogen. Further investigation may lead to the reclassification of this genus within the family *Methanocorpusculaceae*.

Methanocalculus halotolerans. These irregular cocci (0.8–1 µm in diameter; Fig. 12) occur singly or in pairs and possess 2–3 peritrichous flagella. Colonies are round, reaching 1 µm in diameter after 10 weeks incubation at 37°C. Methane is produced from H₂ + CO₂ or from formate. No growth or methane production is detected on acetate, methanol, trimethylamine, lactate, glucose, 1-propanol, 2-propanol, 1-butanol or 2-butanol. Acetate is required for growth stimulated by yeast extract. For growth, the optimum temperature is 38°C (range >24–<50°C); optimum pH is 7.6 (range 7–8.4); optimum NaCl concentration is 5% (range 0–12.5%); the widest reported range to date for any hydrogenotrophic methanogen, including members of the orders *Methanobacteriales*, *Methanococcales* and *Methanomicrobiales*). Minimum generation time is 12 h. The G+C content of DNA is 55 mol% (HPLC). This organism was isolated from an oil-producing well. Its GenBank 16S rRNA sequence accession number is AF033672. It is the type species of genus:

Methanocalculus. The type strain is SEBR 4845^T (OCM 470^T). Refer to Ollivier et al. (1998).

Fig. 12. (a) Phase-contrast micrograph of *Methanocalculus halotolerans* showing irregular coccoid cells; bar = 5 μm ; (b) electron micrograph of an ultrathin section showing the cell wall structure; bar = 0.2 μm . (From Ollivier et al., 1998.)

Methanocalculus pumilus. These irregular cocci (0.8–1 μm in diameter) occur singly or in pairs and are nonmotile. They lyse in 0.01% SDS and under hypotonic conditions. Methane is produced from $\text{H}_2 + \text{CO}_2$ or from formate. No growth or methane production is detected on acetate, methanol, trimethylamine, lactate, glucose, 1-propanol, 2-propanol, 1-butanol or 2-butanol. Acetate is required for growth stimulated by yeast extract. Cells are tolerant to heavy metals. For growth, optimum temperature is 35°C (range 24–45°C); optimum pH is 7 (range 5.5–9); and optimum NaCl concentration is 1% (range 0–7%). The minimum generation time is

12 h. The G+C content of DNA is 51.9 mol% (HPLC). This organism was isolated from a waste-disposal site. Its GenBank 16S rRNA sequence accession number is AB008853. Its type strain is MHT-1^T (\equiv DSM 12632^T or JCM 10627^T). Refer to Mori et al. (2000).

Biochemical and Physiological Properties

Coenzymes and Enzymes Within the Methanomicrobiales

In those Methanomicrobiales that have been tested, the activities of methane biosynthesis enzymes are comparable to those found in other methanogens (Schwörer and Thauer, 1991; Raemakers-Franken et al., 1990; Berk and Thauer, 1997). Specifically, high levels of formyl-methanofuran dehydrogenase, coenzyme F_{420} -dependent methylenetetrahydro-methanopterin dehydrogenase, methylenetetrahydromethanopterin reductase, and heterodisulfide reductase have been found. The proton-reducing methylenetetrahydro-methanopterin dehydrogenase was not found. The Methanomicrobiales also contain high levels of the methyl coenzyme M reductase (Rouvière and Wolfe, 1987). Methanopterin and sarcinapterin are common C-1 carriers in most methanogens. However, the Methanomicrobiales contain three unique pterins in place of methanopterin (Gorris and van der Drift, 1994). Two novel pterins, called “tatiopterin-O” and “tatiopterin-I,” have been isolated and characterized from *Methanofollis tationis* (Raemakers-Franken et al., 1991b). Tatiopterin-I (a methanopterin-like compound) lacks the characteristic methyl group on the 7-position of the pterin and has additional aspartyl and glutamyl residues on the side chain. Tatiopterin-O is similar to tatiopterin-I, except the glutamyl residue is missing from the side chain. In addition, *Methanoculleus thermophilicum* contains a pterin similar to tatiopterin-O, except the aniline moiety contains two hydroxyl residues (Raemakers-Franken et al., 1991a). Interestingly, extracts of *M. hungatei* contain serine hydroxymethyltransferase activity that is dependent on tetrahydrofolate, but not on tetrahydromethanopterin and tetrahydrosarcinopterin (Lin and Sparling, 1998). This observation may indicate that folates are also present in these methanogens. Alternatively, a tatiopterin-dependent enzyme may be present whose substrate specificity includes folate.

The Methanomicrobiales also contain high levels of coenzyme F_{420} and vitamin B_{12} (Gorris and van der Drift, 1994). The predominant coenzymes F_{420-2} and F_{420-3} have two and three

glutamyl residues on their side chains, respectively. Coenzyme F_{420-4} and coenzyme F_{420-5} , which are abundant in the *Methanosarcinales*, are either present at much lower concentrations or absent. Like most methanogens, the Methanomicrobiales contain high levels of the vitamin B_{12} compound, 5-hydroxybenzimidazolcobamide. The ability to utilize alcohols as electron donors for methanogenesis is widely distributed among the Methanomicrobiales (Widdel, 1986; Zellner and Winter, 1987; Widdel et al., 1988). The secondary alcohol dehydrogenases responsible for these activities are either coenzyme F_{420-} or $NADP^+$ -dependent (Bleicher et al., 1989; Frimmer and Widdel, 1989). The coenzyme F_{420-} dependent enzymes have been purified from *M. thermophilicum* and *M. liminatans* (Widdel and Wolfe, 1989; Bleicher and Winter, 1991). In both cases, the enzymes were composed of subunits with an Mr of about 39,000 and were unstable during storage. The enzyme from *M. liminatans* had a broad substrate specificity that included 2-propanol, R(-)-2-butanol, S(+)-2-butanol, 2-pentanol, cyclopentanol, and the corresponding ketones. Like other coenzyme F_{420-} dependent enzymes, the *M. thermophilicum* enzyme possesses Si-face stereospecificity with respect to the C-5 position of coenzyme F_{420} (Klein et al., 1996). The ethanol dehydrogenase activity in extracts of *M. organophilum* has also been characterized (Frimmer and Widdel, 1989). This activity is $NADP^+$ -dependent and has a pH optimum of 10. It also has a Re-face stereospecificity at the C-4 position of $NADP^+$ (Berk et al., 1996). Organisms which utilize the $NADP^+$ -dependent alcohol dehydrogenase also possess high levels of coenzyme F_{420-} dependent $NADP^+$ reductase (Berk

and Thauer, 1997). This enzyme is necessary to couple alcohol oxidation with the coenzyme F_{420-} dependent steps in methanogenesis. The enzyme from *M. organophilum* has been purified and found to be similar in molecular weight and other properties to the enzymes from other methanogens (Berk and Thauer, 1997).

The bioenergetics of the Methanomicrobiales have not been studied in detail. In *Methanospirillum hungatei*, low affinity potassium transport and Na^+/H^+ antiport systems have been described (Sprott et al., 1985; Rusnák et al., 1992).

Cell Envelope Structure

With the exception of *Methanospirillum hungatei*, the cell envelopes of the Methanomicrobiales are composed of a regularly structured protein layer (S-layer) and a cytoplasmic membrane (Sleytr et al., 1986; Sprott and Beveridge, 1993). The S-layer forms a paracrystalline array, usually with hexagonal (p6) symmetry and center-to-center spacing of 14–16 nm (Table 5). The molecular weight and antigenicity of the S-layer proteins vary between species and genera. Except for *Methanogenium cariaci* and *Methanospirillum hungatei*, the S-layer proteins are generally glycosylated. Unlike cells containing pseudomurein in their envelopes, cells where the envelope is composed entirely of a S-layer are frequently sensitive to detergents. The S-layers of *Methanoculleus marisnigri* and *Methanoplanus limicola* have been analyzed in some detail. In *M. marisnigri*, the S-layer-membrane complex forms a tight but noncovalent association that is deformable and not rigid (Bayley and Koval,

Table 5. Envelopes of Methanomicrobiales.

Data from Sprott and Beveridge, 1993.

1994). In *M. limicola*, the molecular architecture of the S-layer was reconstructed from a tilt series of negatively stained preparations and surface relief reconstructions of metal-shadowed preparations as well as from scanning tunneling microscopy (Cheong et al., 1991; Cheong et al., 1993). The surface layer has hexagonal or p6 symmetry, a lattice constant of 14.7 nm, and thickness of approximately 6.5 nm. The S-layer protein has an apparent molecular weight of 135 kDa, shifting to 115 kDa after removal of the carbohydrate components with anhydrous trifluoromethanesulfonic acid. In addition, quantitative estimations revealed a total neutral sugar content of 240 mg/g of polypeptide. To form an irregular coccus (as is common in the Methanomicrobiales), the S-layer must incorporate local faults or edge dislocations in the paracrystalline structure (Pum et al., 1991). Likewise, edge dislocations are required for invagination of the envelope during cell division.

The cell envelope of *Methanospirillum hungatei* has a unique ultrastructure. Cells contain an S-layer similar to that found in other Methanomicrobiales (Firtel et al., 1993; Table 5). Individual cells or chains of cells are then further enclosed by a sheath. Within the chains, cells are separated by a spacer region composed of multiple lamellae or spacer plugs. The sheath is extremely resilient to denaturants, salts, proteases, and other enzymes (Beveridge et al., 1985), but it can be disassociated into hoop structures and free polypeptides by treatment with sulfhydryl reagents (Sprott et al., 1986; Southam and Beveridge, 1991). In addition, about 20% of the mass of the sheath is made up of phenol-soluble proteins that confer rigidity (Southam and Beveridge, 1992). The intact sheath is a paracrystalline array of 2.8-nm particles and is composed of stacked hoops (Stewart et al., 1985; Beveridge et al., 1990; Blackford et al., 1994), and the tight packing of the sheath particles produces a barrier of low porosity that limits the movement of even small molecules (Beveridge et al., 1991). Measurements of the elasticity of the sheath by atomic force microscopy indicate that it can withstand pressures in the range of 300–400 atm (Xu et al., 1996). It is hypothesized that the accumulation of intracellular CH₄ to high pressures causes expansion of the sheath, which opens pores in the sheath and allows the release of CH₄ and uptake of H₂ and CO₂. In this way, the sheath is envisioned to act as a pressure regulator (Xu et al., 1996). In contrast to the sheath, the spacer plugs at the ends of the cell are highly permeable (Beveridge et al., 1991). These plugs are proteinaceous disks that span the sheath and consist of two types of paracrystalline layers sandwiched between amorphous layers of unknown composition (Firtel et al.,

1994). One type of paracrystalline layer is composed of 14-nm particles with 18-nm interparticle spacing to produce a highly porous structure. The second layer is net-like with large, 12.5-nm pores. These layers are attached to each other and the cell by intervening amorphous layers.

Cell Envelope Lipids

Similarly to other methanogens, the cell membranes of Methanomicrobiales are characterized by many unusual lipids. These lipids are polar, either archaeol (diphytanyl-glycerol-diethers) or caldarchaeol (dibiphytanyl-diglycerol-tetraethers). Caldarchaeol appears to span the membrane, with the polar head groups at opposite sides. Therefore, the membranes are probably arranged in a monolayer with bilayer regions resulting from interspersed diethers (Whitman et al., 1992). These lipids are then present as phospho- or glyco-derivatives. Among the Methanomicrobiales, the major sugars in the glycolipids are glucose (glc) and galactose (gal; Koga et al., 1998). The major polar head groups in the phospholipids are aminopentametrols and glycerol. In *Methanospirillum hungatei*, four of the polar lipids had as one head group either α -glc(p)-(1-2)- β -gal(f)- or β -gal(f)-(1-6)- β -gal(f)- in glycosidic linkage to the first glycerol of the lipid backbone and either a *N,N*-dimethylaminopentametrol or a *N,N*-trimethylaminopentametrol moiety in phosphodiester linkage to the second glycerol of the backbone (Sprott et al., 1994). A fifth lipid was a tetraether structure with carbohydrate moieties at both head group positions, namely α -glc(p)-(1-2)-gal(f) and β -gal(f)-. Two other lipids, a diether and a tetraether, had a single head group consisting of α -glc(p)-(1-2)- β -gal(f)- modified by O-acetylation of the gal(f) residue at C-6. Lastly, the diether and tetraether analogs of phosphatidylglycerol were found.

Motility

Flagella are observed in species of the order Methanomicrobiales. In *Methanospirillum hungatei* mono- or bipolar flagella are inserted through the end plugs of the filaments (Cruden et al., 1989; Southam et al., 1990). Filaments, with a tuft of flagella at each of the terminal cells on opposite ends of the filament, are able to coordinate flagellar rotation so that propulsion is achieved (Sprott and Beveridge, 1993). Isolated flagellar filaments from *Methanospirillum hungatei* can be dissociated by low concentrations (0.5% [v/v]) of Triton X-100 (Faguy et al., 1992). The filaments are composed of multiple glycosylated flagellins, where the flagellins represent distinct gene products rather than differentially glycosylated forms of the same protein. Similarly,

the purified flagellar filaments isolated from *Methanoculleus marisnigri* were shown to be composed of two flagellins (Kalmokoff et al., 1992). Lastly, the flagellar filaments have a simple knob basal structure with no apparent ring or hook structures such as found in bacteria (Faguy et al., 1994). When cultivated at 37°C, *Methanospirillum hungatei* grows as single cells or short chains of cells (typically 10–30 µm long), and both forms are motile. When grown in low Ca²⁺ concentrations or with the divalent cation chelator EDTA, nonflagellated filaments (up to 900 µm long) are produced. Likewise, at sub-optimal growth temperatures, the cells form short filaments that do not possess flagella. The amount of flagellin present appears to be equal in both nonflagellated and flagellated cultures (Faguy et al., 1993).

Compatible Solutes

Methanogens respond to osmotic stress by accumulating a series of organic molecules which function as compatible solutes. Four key organic solutes were observed in *Methanogenium cariaci*. They include L-α-glutamate, β-glutamate, N(e)-acetyl-β-lysine and betaine. Though L-α-glutamate, β-glutamate and N(e)-acetyl-β-lysine are synthesized de novo, betaine is preferentially assimilated from the medium (Robertson et al., 1992). In the absence of betaine, N(e)-acetyl-β-lysine is the dominant osmolyte.

Miscellaneous

Methanomicrobium mobile is light sensitive. Growth is inhibited by light in the blue end of the visible spectrum (370 to 430 nm; Olson et al., 1991).

The Order Methanobacteriales

ADAM S. BONIN AND DAVID R. BOONE

Characteristics of Methanobacteriales

Members of the order Methanobacteriales are distinguished from other methanogens by their limited range of catabolic substrates, their morphology, lipid composition, and rDNA sequence. The Methanobacteriales are generally hydrogenotrophic, using H_2 to reduce CO_2 to CH_4 . Some members of this order can use formate, CO , or secondary alcohols as electron donors for CO_2 reduction. However, members of one genus within this order, *Methanosphaera*, use H_2 to reduce methanol to methane. The predominant cell wall polymer of *Methanobacteriales* is pseudomurein, which distinguishes this order from the Methanomicrobiales. Lipids composing the cell membranes include caldarchaeol and *myo*-inositol. Cells usually stain Gram positive and are generally rod-shaped, often forming chains or long filaments up to 40 μm in length. The order Methanobacteriales is divided into two families, the Methanobacteriaceae and Methanothermaceae, on the basis of phylogenetic analysis of 16S rRNA gene sequences as well as phenotypic characteristics (Boone, 2001).

Habitats of Methanobacteriales

Similarly to other methanogenic orders, members of the Methanobacteriales are very strict anaerobes inhabiting a variety of anoxic habitats including freshwater and marine sediments, groundwater, rice paddy fields, terrestrial subsurface environments, anaerobic sewage digestors, environments containing accumulated geothermal H_2 , and the gastrointestinal tracts of animals. Specific habitats known to harbor specific strains are indicated below in the sections describing each species.

Isolation and Characterization

Enrichment Media for Growth of Methanobacteriales

MS Mineral Medium and MS Medium are appropriate for the growth of Methanobacteriales. The recipes for these media are given below. MS Mineral Medium with H_2 added as a catabolic substrate is an effective medium for the enrichment of autotrophic members of this order. MS Medium, which contains yeast extract and trypticase peptones (2 g each per liter), is recommended for the enrichment of species that have organic nutrient requirements. Reducing the concentrations of yeast extract and trypticase peptones to 0.5 g of each per liter (MS Enrichment Medium) can reduce the numbers of heterotrophic bacteria growing in enrichment cultures. The use of the higher concentrations of organic compounds in MS medium has some advantages in the routine cultivation of pure cultures: it is easy to detect the growth of heterotrophic contaminants, when they occur, in this rich medium.

The Methanobacteriales generally grow and produce methane by reducing CO_2 with H_2 , although some cells can use formate, CO , secondary alcohols, or methanol as electron donor. Species of *Methanosphaera* grow only by reducing methanol to methane, with H_2 as the electron donor.

MS Medium (Boone et al., 1989)

$NaHCO_3$	0.1 mol
Yeast extract	2.0 g
Trypticase peptones	2.0 g
Mercaptoethanesulfonic acid	0.5 g
$Na_2S \cdot 9H_2O$	0.25 g
NH_4Cl	1.0 g
$K_2HPO_4 \cdot 3H_2O$	0.4 g
$MgCl_2 \cdot 6H_2O$	1.0 g
$CaCl_2 \cdot 2H_2O$	0.4 g
Resazurin	1.0 mg
Trace mineral solution (see below)	10 ml

Instead of $NaHCO_3$, an equimolar amount of $NaOH$ equilibrated with CO_2 may be added. Dissolve all ingredients and dilute up to 1 liter with distilled water.

Table 1. Distinguishing features of Methanobacteriales.

Feature	Methanobacteriales	Methanococcales	Methanomicrobiales	Methanosarcinales	Methanopyrales
Morphology	Rod, coccus, and rarely coccobacillus	Irregular coccus	Small rod, plate, irregular coccus, and curved rod	Irregular coccus sometimes in aggregates, rod, and flat polygon	Rod
Substrates ^a	H ₂ (for, alc, methanol)	H ₂ (for)	H ₂ (for, alc)	(me, H ₂ , ac)	H ₂
Motility	+/-	+	+/-	-	+
Temperature range, °C	15–97	18–94	0–60	2–70	84–110
Cell wall	Pseudomurein	Protein	Glycoprotein (sheath)	Glycoprotein (methanochondroitin, sheath)	Pseudomurein
Distinctive lipid components	Caldarchaeol and <i>myo</i> -inositol	Serine	Galactose, aminopentetetrols, and glycerol	Hydroxyarchaeol, <i>myo</i> -inositol, ethanolamine, and glycerol	Galactose and mannose
Mol% G + C	23–61	30–33	38–61	36–54	60

Symbols: +, present in most or all taxa; –, present in a few or no taxa; and +/-, present in many but not all taxa.

Abbreviations: for, formate; alc, alcohols; me, methylamines; and ac, acetate.

^aSubstrates (in parentheses) are utilized by many but not all taxa.

Adapted from Garcia et al. (2003).

Table 2. Some characteristics of the Methanobacteriales families.

Family	Characteristics
Methanobacteriaceae	Short lancet-shaped cocci, short-to-long rods, or filamentous rods; substrates for methanogenesis are H ₂ + CO ₂ , formate and CO (which may also be oxidized), methanol (which may be reduced), and secondary alcohols + CO ₂ ; cells typically stain Gram positive; nonmotile; little or no growth above 70°C; and G+C content, 23–61 mol%.
Methanothermaceae	Single rods and short rod chains; substrates for methanogenesis are H ₂ + CO ₂ ; stain Gram positive; motile; no growth below 60°C and optimal growth generally above 70°C; and G+C content, 33 mol%.

Trace Mineral Solution (adapted from Ferguson and Mah, 1983)

NaEDTA · 2H ₂ O	500 mg
CoCl ₂ · 6H ₂ O	150 mg
MnCl ₂ · 4H ₂ O	100 mg
FeSO ₄ · 7H ₂ O	100 mg
ZnCl ₂	100 mg
AlCl ₃ · 6H ₂ O	40 mg
Na ₂ WO ₄ · 2H ₂ O	30 mg
CuCl	20 mg
Ni ₂ SO ₄ · 6H ₂ O	20 mg
H ₂ SeO ₃	10 mg
H ₃ BO ₃	10 mg
Na ₂ MoO ₄ · 2H ₂ O	10 mg
Dissolve in 1 liter of distilled water and adjust pH to 3.0 with HCl.	

MS Mineral Medium

This is MS medium without any mercaptoethanesulfonate, trypticase peptones, or yeast extract. Sulfide is increased to 0.5 g per liter.

Prepare medium by first dissolving the sodium bicarbonate (or NaOH) in oxygen-free water equilibrated with CO₂ gas. For MSH Medium, the water should also contain 87.75 g (1.5 mol)

of NaCl, 5 g of MgCl₂ · 6H₂O, and 1.5 g of KCl per liter. Then add yeast extract and trypticase peptones to a flask flushed with CO₂ followed by CO₂-saturated NaHCO₃ solution, and bubble CO₂ or a gas mixture containing N₂ and CO₂ through the liquid while the other constituents of the medium are added. For convenience, use stock solutions of minerals. Per liter of medium, add 10 ml of solution A (100X, which is per liter: NH₄Cl, 100 g; MgCl₂ · 6H₂O, 100g; CaCl₂ · 2H₂O, 40 g; adjust to pH 4 with HCl), 2 ml of solution B (500X, which is per liter: K₂HPO₄ · 3H₂O, 200 g), 2 ml of solution C (500X, which is per liter: resazurin, 0.5 g), and 10 ml of the trace mineral solution (described above). Store these solutions as anoxic, nonsterile solutions at room temperature.

Add any soluble substrates, such as sodium formate or methanol, prior to dispensing the medium into individual vessels, or add these later as sterile anoxic stock solutions. Add mercaptoethanesulfonic acid, a reducing agent, prior to dispensing the medium to individual vessels. Add Na₂S only after dispensing the medium and sealing the vessels because H₂S is volatile. In general

Abbreviation: ^T, type family of the order, type genus of the family, or type species of the genus.

add as a sterile, anoxic stock solution (usually 2.5%) just prior to using the medium. Use CO₂ or a mixture containing N₂ and CO₂ to flush individual vessels. To control the pH (which is ca. 6.7 with 100% CO₂ and 7.1 with 30% CO₂) adjust the proportion of CO₂ in the gas phase.

Add insoluble constituents such as agar or cellulose to the medium and mix with a magnetic stirrer while dispensing. Alternately, weigh such materials in individual vessels and then suspend them in the appropriate volume of medium.

Modifications of Media

Medium can be modified for experiments by direct additions to individual vessels. Substrates can also be added from sterile, anoxic stock solutions. When many vessels with the same substrate are desired, the substrate can be added to the medium before it is dispensed. For gaseous substrates such as H₂, pure gas may be added as an overpressure after inoculation (it is difficult to inoculate tubes which have been pressurized). H₂ mixtures with CO₂ should not be used during

this initial pressurization because this would change the pH of the medium. To restore H₂ levels depleted during growth of H₂-using methanogens, it should be added in a 3 : 1 mixture of H₂ and CO₂ with shaking. Adding this gas while maintaining the same pressure used for the initial pressurization re-establishes the proper pH and CO₂ content of the gas.

Solutions for addition to individual vessels of medium should normally be prepared at a concentration about 50-fold greater than that desired in the medium and at a neutral pH (e.g., organic acids should normally be added as sodium salts). By using 50X solutions, a convenient amount (0.1 ml per 5-ml tube) can be added to serum tubes or serum bottles or even to medium during preparation. However, stock solutions of higher concentrations may be more convenient for larger vessels (e.g., for 50 ml of medium, 1 ml of a 50X solution would be required; 0.2 ml of a 250X solution may be more convenient). Solutions may be prepared in a manner similar to that used for medium preparation, by dissolving components in anoxic water, sealing, and autoclaving.

Table 4. Some characteristics of methanogenic archaea of the order Methanobacteriales.

^aRefers to strain AZ.

^bRefers to strain PS.

Data in this table are from references cited in sections of this chapter describing individual species.

Removal of liquid from vials of stock solution results in decreased gas pressure. To prevent the development of negative pressure (which could result in oxygen entering the vial), these vials may be pressurized to about 35 kPa (5 psig

[pounds per square inch gauge]) overpressure of N₂.

In some cases with large vessels it may be convenient to add directly very concentrated substrates from solutions or liquids without first

flushing to remove oxygen. For instance, to add 100 mM methanol to a 50-ml serum bottle, one could add 0.202 ml of pure methanol. Pure methanol is sterile (when removed from the bottle with sterile syringe) and 0.2 ml contains an insignificant amount of O₂. Acids also may be added this way and neutralized in the medium by addition of sterile, oxygen-free sodium hydroxide solution.

Sulfide solution is generally added to medium about 1 to 24 h before use. For agar slants to be used within a week, the sulfide can be added prior to autoclaving. However, sulfide should always be added to individual vessels and not to the medium in the flask. At neutral pH values, dissolved sulfide is in equilibrium with gaseous H₂S, so it gradually would be lost while the flask was flushed with N₂ and CO₂. If slants are to be stored for more than one week before inoculation, the sulfide should be added the day before inoculation; it may be added without re-melting the slants. For roll tubes to be used on the day of preparation, sulfide may be added to individual tubes before autoclaving. If the roll-tube media will be stored, the sulfide may be added later, either before or after melting the agar.

Sulfide solution should be prepared in oxygen-free water. Removal of oxygen from water may be accomplished by boiling or by flushing with oxygen-free (and CO₂-free) gas.

To prepare sulfide solution in boiled water, add 100 ml of distilled water to a 250-ml flask, add boiling chips, and mark the level in the flask. Add about 10 ml of water and boil to the mark. When the level approaches the mark, begin flushing with oxygen-free N₂ gas. (It is important not to use mixtures containing CO₂! This would acidify the sulfide solution, converting sulfide to H₂S, which is volatile.) Place a stopper into the neck of the flask and cool the water while flushing the flask.

To prepare sulfide in water deoxygenated by flushing with gas, bubble with N₂ for 30 min.

Weigh out 2.5 g of Na₂S · 9H₂O, choosing large, clear crystals. Clean small, wet, or off-color crystals by immersing them in distilled water for a short time, followed by drying with tissue or a paper towel. Add the sulfide to the oxygen-free water and swirl to dissolve. Dispense, seal, and autoclave. Never boil the sulfide solution. Use or discard the solution within 4 weeks.

Enrichment, Isolation and Characterization

Members of the *Methanobacteriales* may be enriched and subsequently isolated from the environment by using serum-tube modifications of the Hungate technique developed for the cultivation of strictly anaerobic bacteria (Hungate, 1969; Miller and Wolin, 1974; Balch and Wolfe,

1976). All genera within this order can grow with H₂/CO₂, with the exception of species within the genus *Methanospaera*, which require H₂ and methanol. This characteristic distinguishes this genus from all other methanogens. Therefore, H₂ added to the headspace of serum tubes containing MS Medium (which also contains CO₂) provides effective conditions for the enrichment of most members of this order. However, for the enrichment of *Methanospaera*, a 10% inoculum from an environmental sample into MS Medium with 0.6% methanol (Boone, 2001) and added H₂ in the headspace is effective. MS Medium and MS Mineral Medium can be employed in separate culturing vessels during enrichment so that autotrophic and heterotrophic methanogens can be concomitantly cultivated from the environment. MS Mineral Medium will allow for the enrichment of autotrophs while preventing heterotrophs from potentially outcompeting or overwhelming the culture. For more successful enrichments and isolations, it is recommended that the medium be prepared to simulate the chemical conditions of the environment sampled.

Acetogenic bacteria can grow faster and use H₂ plus CO₂ (H₂/CO₂) faster than can methanogens. Sequential transfer of enrichment cultures containing both acetogens and methanogens can result in eventual outcompetition by the acetogens. Often the initial number of methanogens is greater, so outcompetition of acetogens can be avoided by an initial dilution series so that higher dilutions contain methanogens but not acetogens. When acetogens are initially present in equal or greater numbers, the recovery of methanogens may require the use of antibiotics to suppress growth of acetogens.

Isolations are accomplished by the Hungate roll tube technique for strict anaerobes (Hungate, 1969). However, some *Methanobacteriales*, such as *Methanothermobacter fervidus*, cannot grow on agar (Stetter et al., 1981). *Methanothermobacter fervidus* can be isolated by picking individual colonies from medium 1 (Balch et al., 1979), which uses polysilicate rather than agar for solidification. To ensure purity, cultures obtained by picking colonies from roll tube media should be subjected to the procedure a second time.

Guidelines for the characterization of new taxa of methanogens have been proposed (Boone and Whitman, 1988). These minimal standards include the employment of a pure culture to determine the cellular morphology, colony morphology on or within a solid surface, susceptibility to lysis, Gram stain reaction, substrate range, product formation, and nutrient requirements and the measurement of growth rate under various growth conditions supporting growth and methanogenesis. The range and opti-

mum values of pH, temperature, and salinity (NaCl) should be determined. Elements of the physiological characterization (not required but highly recommended) include the determination of G+C content of the DNA, electron microscopy, antigenic fingerprinting, lipid analysis, protein analysis, and nucleic acid hybridization and sequencing. However, it should be noted that a phylogenetic analysis of the 16S rRNA gene sequence is paramount when making taxonomic determinations. In this analysis, 16S rRNA gene sequences are aligned and compared with those within GenBank® or other databases.

The Family Methanobacteriaceae

The family Methanobacteriaceae is represented by four genera including *Methanobacterium*, *Methanobrevibacter*, *Methanosphaera* and *Methanothermobacter*. Members of this family are very strict anaerobes and all grow by oxidizing H₂, although some species may also oxidize formate and/or CO. The terminal electron acceptor is CO₂ for all Methanobacteriaceae except members of the genus *Methanosphaera*, which reduce methanol. The microbes of this order are widely distributed in nature and rarely exist in systems that exceed 70°C.

Methanobacterium

The genus *Methanobacterium* is represented by nine species described below. Members of this genus are rod-shaped mesophiles that grow by reducing CO₂ with H₂ usually; however, some strains can use formate, secondary alcohols, and CO as electron donors. A tenth species, *Methanobacterium thermoaggregans*, a thermophilic autotrophic methanogen recovered from a cattle pasture mud sample, was reported in 1985 (Blotevogel and Fischer, 1985). However, this organism was obtained via a highest dilution strategy and was not isolated from a single cell or colony. Therefore, *M. thermoaggregans* was not included as a species within this genus in the second edition of *Bergey's Manual for Systematic Bacteriology* (Boone, 2001) or in this chapter of *The Prokaryotes*.

METHANOBACTERIUM FORMICICUM. The type strain of this species was isolated from a liquid sewage sludge sample collected from a domestic anaerobic digester in Urbana, Illinois in 1966 (Bryant and Boone, 1987). This organism may be found at high densities in anaerobic digestors and freshwater sediments. This species has also been reported to be present at low densities in cattle rumen (van Bruggen et al., 1984) and within the anaerobic ciliate, *Metopus striatus*, where it survives as an endosymbiont

(Magingo and Stumm, 1991). Cells of this organism are long crooked rods, occurring singly and often forming rod chains and filaments. CO₂ may be reduced with H₂ or formate to support growth and methanogenesis. Some strains may be autotrophic, and acetate and cysteine are often stimulatory. The type strain of this species is strain MF (DSM 1535).

The literature regarding the type strain of this species is somewhat confusing. The species was originally described by Schnellen (1947), but the type strain was lost. Another strain was isolated and characterized by Mylorie and Hungate (1954), but that strain was also lost. Later, strain MF was isolated by Marvin Bryant (Bryant and Boone, 1987), and this strain was widely regarded as the type strain of *Methanobacterium formicicum*, although this was never formalized. Later, the *Approved Lists* (Skerman et al., 1989) incorrectly designated strain M.o.H. as the type strain of *Methanobacterium formicicum*. Subsequently, an Opinion of the Judicial Commission corrected the errors by making strain MF the neotype strain of *Methanobacterium formicicum* and assigning strain M.o.H. as the type strain of *Methanobacterium bryantii* (Boone, 1987; Judicial Commission, 1992).

METHANOBACTERIUM ALCALIPHILUM. Four alkaliphilic strains of this species were isolated from the sediments of four high-pH lakes in the Wadi el Natrum of Egypt (Worakit et al., 1986). Prior to the discovery of this species, the majority of methanogens identified had been shown to grow at pH values near neutrality. *Methanobacterium alcaliphilum* not only grows at high pH values, but prefers such conditions, growing fastest at pH values between 8.1 and 9.1. Cells of this organism tend to be long rods, occurring singly or in pairs and rarely in chains or filaments. H₂/CO₂ are the sole substrates supporting growth and methanogenesis. Components of yeast extract and/or peptones are required nutrients. The type strain of this species is WeN4 (DSM 3387).

METHANOBACTERIUM BRYANTII. This methanogen was separated and subsequently isolated from a syntrophic coculture containing *Methanobacillus omelianskii*, which was originally enriched from an anaerobic digester (Bryant et al., 1967). This strain may also be found in freshwater sediments. Cells are generally rods with blunt, rounded ends often forming irregular or crooked chains and filaments. H₂/CO₂ are the sole substrates supporting growth and methanogenesis. Components of yeast extract and/or trypticase peptones are required for growth. Strain M.o.H. (DSM 863) is the type strain of *Methanobacterium bryantii*, but the *Approved Lists* (Skerman et al., 1989) incorrectly designated this strain as the type strain of

Methanobacterium formicicum. This error made *M. bryantii* a junior objective synonym of *M. formicicum*. The problem was subsequently resolved by an Opinion of the Judicial Commission that made strain MF the neotype strain of *Methanobacterium formicicum* and reinstated *M. bryantii* with strain M.o.H. as the type strain (Boone, 1987; Judicial Commission, 1992).

METHANOBACTERIUM CONGOLENSE. This organism was isolated from an anaerobic digester that was fed raw cassava peel in the Congo of Central Africa in 1992 (Cuzin et al., 2001). Cells are rod-shaped, usually occurring individually or in pairs though infrequently forming chains. H_2/CO_2 are the sole substrates supporting autotrophic growth; however, methane may be produced from 2-propanol/ CO_2 , 2-butanol/ CO_2 , and cyclopentanol/ CO_2 without supporting growth. Strain C (DSM 7095) is the type strain of *M. congolense*.

METHANOBACTERIUM ESPANOLENSE. This moderately acidiphilic methanogen (optimum pH is between 5.6 and 6.2, though no growth occurs below pH 4.7) was isolated from an anaerobic digester degrading solids from a bleach-craft mill in Espanola, Ontario, Canada (Patel et al., 1990). Cells are rod-shaped, often forming chains and filaments. H_2/CO_2 are the sole substrates supporting growth and methanogenesis. Vitamins may be stimulatory though it appears that this organism is autotrophic, which has yet to be confirmed. Further, *M. espanolense* was shown to grow in minimal medium containing acetate (Boone, 2001). The type strain of this species is strain GP9 (NRC 5912 = DSM 5982).

METHANOBACTERIUM IVANOVII. The interest in methanogenesis in deep subsurface environments led to the discovery of this species within an oil-bearing sedimentary rock core from 1650 m deep in the Bondyuzshkoe oil field in the former Soviet Union. This location represents the deepest natural habitat providing a methanogenic isolate. This strain is similar to *Methanobacterium bryantii*, but is sufficiently distinct (both phenotypically and phylogenetically) to be considered as a separate species (Jain et al., 1987). Cells are rod-shaped and tend to grow singly or in groups of 2–3, not forming chains or filaments. H_2/CO_2 are the sole substrates supporting autotrophic growth and methanogenesis. Growth is stimulated with acetate. The type strain of this species is Ivanov (DSM 2611).

METHANOBACTERIUM ORYZAE. This species was isolated from rice field soil in the Philippines (Joulian et al., 2000), a habitat often exploited by the strictly-anaerobic methanogens. Rod-shaped cells occur individually and often form long chains up to 40 μm in length. *Methanobacterium*

Fig. 1. Phase-contrast micrograph of *Methanobacterium oryzae*, strain FPi, showing long cell chains. Bar = 10 μm . Courtesy of Joulian et al. (2000).

nobacterium oryzae can grow by using H_2/CO_2 or formate. *Methanobacterium oryzae* is an autotroph, though its growth is stimulated by yeast extract. The type strain of this species is FPi (DSM 11106).

METHANOBACTERIUM PALUSTRE. This organism was isolated from a peat bog marshland of the Sippenauer Moor, Germany, and described in 1989 (Zellner et al., 1989). Substrates supporting growth include H_2/CO_2 and formate. In addition, 2-propanol/ CO_2 and 2-butanol/ CO_2 can be utilized as catabolic substrates; however, the use of these alcohols does not lead to measurable growth (Zellner et al., 1989). *Methanobacterium palustre* does not require growth factors. Cells are rod-shaped, sometimes forming filaments up to 65 μm long. Strain F (DSM 3108) is the type strain of this species.

METHANOBACTERIUM SUBTERRANEUM. Three strains of this species were isolated from deep granitic rock groundwater under the island of Aspo within the hard rock laboratory tunnel in southeastern Sweden following sample collections from 1995 to 1996 (Kotelnikova et al., 1998). Cells are small, thin rods, often growing in aggregates (Fig. 2) but not in chains or filaments. Catabolic substrates include H_2/CO_2 and formate in minimal medium, therefore supporting autotrophic growth. The type strain of this species is A8p (DSM 11074).

METHANOBACTERIUM ULIGINOSUM. This organism was isolated from marshy soil (König, 1984). H_2/CO_2 is the sole catabolic substrate regime supporting its autotrophic growth. Cells are rod-shaped with an irregular cell surface, and spherical cells are often produced at the ends of some rods, which are either retained or

Fig. 2. Electron micrographs of cell thin sections (a–c) and phase-contrast micrograph showing cell aggregation in culture of *Methanobacterium subterraneum*. Bar = 50 nm in (a) and (b); bar = 100 nm in (c); and bar = 1 μ m in (d). Abbreviations include M, cytoplasmic membrane; CW, cell wall; CP, cytoplasm; IN, invagination of cytoplasmic membrane prior to binary fission; and S, septum. Courtesy of Kotelnikova et al. (1998).

released in culture. The type strain of this species is P2St (DSM 2956).

Methanobrevibacter

The genus *Methanobrevibacter* includes the twelve species described below.

METHANOBREVIBACTER RUMINANTUM. This species, the type species of the genus *Methanobrevibacter*, was isolated from a bovine rumen and is the first methanogen to be isolated using H_2 as a catabolic substrate for isolation (Smith and Hungate, 1958). Previous isolations relied on soluble substrates contained in deep agar, making the exclusion of O_2 less difficult. Substrates supporting methanogenesis include H_2/CO_2 and formate. However, this species also requires acetate as a major cell carbon source (Bryant et al., 1971) and has complex nutritional requirements including amino acids, at least one B vitamin, 2-mercaptoethanesulfonic acid (coenzyme M), and 2-methylbutyric acid (Bryant, 1965; Bryant et al., 1971; Taylor et al., 1974). The type strain of this species is M1 (DSM 1093).

METHANOBREVIBACTER ACIDIDURANS. This methanogen was isolated from a distillery waste anaerobic digester, which was initially seeded with cattle dung, and developed in the laboratory (Savant et al., 2002). Strain ATM (DSM 15163) is the type strain and the only strain of *M. acididurans*. It was enriched from a sour acidogenic digester (pH 5) and is acid-tolerant, growing fastest at pH 6. H_2/CO_2

are the only catabolic substrates supporting growth, which occurs only in the presence of acetate, rumen fluid, and a mixture of amino acids. The rumen fluid appears to supply an unknown growth factor. Cells are coccus-shaped, occurring singly or in pairs and/or chains (Fig. 3).

METHANOBREVIBACTER ARBORIPHILUS. Five strains of *Methanobrevibacter arboriphilus* have been isolated and characterized from a variety of anoxic habitats. The type strain, strain DH1 (DSM 1125), was isolated from an enrichment of decaying wetwood tissue of a cottonwood tree (Zeikus and Henning, 1975). The four other strains were isolated from anaerobic sewage sludge (strains AZ and A2), a laboratory-scale anaerobic digester (strain DC), and a rice paddy soil (strain SA). Cells are short rods with rounded ends, occurring singly or in pairs. Nutritional requirements include at least one B vitamin for growth; trypticase peptones, yeast extract, and rumen fluid are stimulatory. Two strains, A2 and SA, can catabolize formate as well as H_2/CO_2 (Asakawa et al., 1993).

METHANOBREVIBACTER CURVATUS. One strain of *Methanobrevibacter curvatus*, type strain RFM-2 (DSM 2462), was isolated from the termite hindgut of *Reticulitermes flavipes* (Leadbetter and Breznak, 1996). Cells are curved rods with tapered ends, occurring singly or in pairs. This species can utilize H_2/CO_2 only as catabolic substrates. Nutritional requirements are complex, including rumen fluid extract and nutrient broth.

Fig. 3. (a) Fluorescence micrograph of *Methanobrevibacter acididurans* showing cellular morphology and cell chains. Bar = 25 μm . (b) Electron micrograph of cell chain. Bar = 1 μm . Courtesy of Savant et al. (2002).

METHANOBREVIBACTER CUTICULARIS. One strain of this species, type strain RFM-1 (DSM 11139), was isolated from the termite hindgut along with *Methanobrevibacter curvatus*, strain RFM-2 (Leadbetter and Breznak, 1996). Cells are short rods with tapered ends, occurring singly, in pairs, or in chains. Unlike *M. curvatus*, this species can use formate as well as H_2/CO_2 as catabolic substrate; however, growth is poor on formate. This species does not require any growth factors, which further distinguishes it from *M. curvatus*. In addition, its optimal temperature is 37°C, in contrast to the 30°C optimal temperature for *M. curvatus*.

METHANOBREVIBACTER FILIFORMIS. This is a third species of *Methanobrevibacter* whose type strain, strain RFM-3 (DSM 11501), was isolated from the subterranean termite, *Reticulitermes flavipes* (Leadbetter et al., 1998). The cellular morphology of this strain differed from those of the other two species from the

termite. This species forms long filaments >50 μm in length. H_2/CO_2 are the sole substrates used for methanogenesis. Yeast extract is required for growth. This species was determined to be the most dominant methanogen within the particular sample of termite hindgut examined from Woods Hole, Massachusetts. However, samples analyzed from other geographic locations do not consistently yield cells or molecular evidence of *M. filiformis*.

METHANOBREVIBACTER GOTTSCALKII. Lin and Miller (1998) reported the phylogenetic analyses and comparisons of several species of *Methanobrevibacter* isolated from animal feces. *Methanobrevibacter gottschalkii* as well as three other species within this genus (*Methanobrevibacter thaueri*, *M. woesei* and *M. wolinii*) is a unique species (Miller and Lin, 2002). The type strain HO (DSM 11977) was isolated from enrichments of horse feces, and another strain of this species, strain PG, was isolated from the feces of a pig. Cells are coccobacilli, occurring in pairs or short chains. Growth and methanogenesis are supported by H_2/CO_2 only (Miller et al., 1986). Nutritional requirements include acetate and/or components of yeast extract or trypticase peptones. Growth is effectively maintained in salt concentrations approaching that of seawater.

METHANOBREVIBACTER ORALIS. Ferrari et al. (1994) isolated the type strain of this species, strain ZR (DSM 7256), from human subgingival plaque. Cells are short rods with tapered ends often occurring in pairs and/or short rod chains. *Methanobrevibacter oralis* is slightly smaller than other species of this genus, and its cell wall is tristratified with deep invaginations, similar to those of *M. ruminantium*. In contrast, a monostratified wall has been reported in other *Methanobrevibacter* species including *M. smithii* and *M. arboriphilicus*. H_2/CO_2 are the sole substrates supporting growth and methanogenesis. Fecal extract is a required nutrient, and a volatile fatty acid mixture enhances growth.

METHANOBREVIBACTER SMITHII. The type strain of this species, strain PS (DSM 861), was isolated from an anaerobic sewage-sludge digester (Miller et al., 1982). However, additional strains have been isolated from human feces. Cells are short oval rods occurring most often in pairs or chains of 4–6 rods. H_2/CO_2 and formate are utilized as substrates, although the latter does not support measurable growth. Acetate is required as a major source of cell carbon and at least one B vitamin is stimulatory for growth.

METHANOBREVIBACTER THAUERI. The type strain, CW (DSM 11995), was isolated from an enrichment of cow feces (Miller and Lin, 2002). Cells are coccobacilli, occurring in pairs

and short chains. H_2/CO_2 support growth and methanogenesis (Miller et al., 1986). Nutritional requirements include acetate for cell carbon and at least one component from either yeast extract or trypticase peptones. Cells grow in salt concentration comparable to that of seawater.

METHANOBREVIBACTER WOESII. This methanogen was isolated from an enrichment of goose feces (Miller et al., 1986). The type strain, strain GS (DSM 11979), is a coccobacillus that occurs in pairs or in short chains. *Methanobrevibacter woesii* grows and produces methane with H_2/CO_2 only and grows well at salt concentration similar to that of seawater. Acetate and at least one component of yeast extract or trypticase peptones are required for growth.

METHANOBREVIBACTER WOLINII. This organism was enriched and isolated from sheep feces (Lin and Miller, 1998). Similar to *M. thaueri*, the type strain, SH (DSM 11976), does not grow in medium with salt concentrations approaching those of seawater. Cells are coccobacilli with tapered or rounded ends, occurring in pairs or short chains. Similarly to *M. gottschalkii*, *M. thaueri* and *M. woesii*, this organism requires acetate and/or one or more components of yeast extract or trypticase peptones. However, nutritional requirements may also include coenzyme M and branched-chain fatty acids.

Methanosphaera

Genus *Methanosphaera* comprises two species, *Methanosphaera stadtmanae* and *Methanosphaera cuniculi*. Members of this genus are spherical chemorganotrophic methanogens requiring methanol and H_2 to support growth and methanogenesis. In contrast, the majority of methanogens isolated from the rumen and gastrointestinal tract of animals utilize H_2/CO_2 for growth and methanogenesis. CO_2 and acetate are required as cell carbon sources.

METHANOSPHERA STADTMANAE. This species, the type species of the genus *Methanosphaera*, was isolated from human feces and therefore most likely inhabits the human large intestine (Miller and Wolin, 1985). Cells are spherical and occur in pairs, tetrads, and aggregates. A cleavage furrow in rapidly dividing cells is visible via electron microscopy as are inclusion bodies (Fig. 4). Methanol is reduced to methane with H_2 . Thiamine, acetate, and CO_2 are required as nutrients; biotin is highly stimulatory. The type strain of this species is MCB3 (DSM 3091).

METHANOSPHERA CUNICULI. The type strain of this organism, 1R7 (DSM 4103), was isolated from the intestinal tract of a rabbit (Biavati et al., 1988). Cells are round and frequently occur in pairs. Methanol and H_2 are the only substrates that support growth and metha-

nogenesis consistent with this genus. Acetate is required for growth; however, other potential nutritional requirements contained in complex rumen fluid medium, which is routinely employed for the cultivation of this organism, have not yet been evaluated.

Methanothermobacter

The genus *Methanothermobacter* is represented by the six species described below. Members of this genus are thermophilic and generally grow optimally between 55°C and 65°C. H₂/CO₂ are used as substrates for methanogenesis and growth. In addition, some strains can use formate to reduce CO₂ to form methane.

METHANOTHERMOBACTER THERMAUTOTROPHICUS. This species, originally included in the genus *Methanobacterium*, was isolated from sewage sludge and reported and described by Zeikus and Wolfe (1972). Cells are irregularly-shaped crooked rods, often forming long filaments up to 120 µm long. As the species name indicates, this organism is autotrophic and thermophilic; therefore it does not require organic growth factors and inhabits environments at elevated temperatures, such as thermophilic anaerobic sewage-sludge digestors. H₂/CO₂ are primarily utilized for methanogenesis and growth; however, some strains can also use formate to reduce CO₂. Strain ΔH (DSM 1053) is the type strain of this species, which is the type species of the genus *Methanothermobacter*.

METHANOTHERMOBACTER DEFLUVII. This organism was isolated from an anaerobic sewage sludge digester and may often be found in such environments (Kotelnikova et al., 1993). Cells are curved or crooked rods. The type strain is ADZ (DSM 7466).

METHANOTHERMOBACTER MARBURGENSIS. Originally, strain Marburg (the type strain of *Methanothermobacter marburgensis* [DSM 2133]) was included as a strain of *Methanothermobacter thermautotrophicum* (previously *Methanobacterium thermoautotrophicum*). However, Wasserfallen et al. (2000) used phylogenetic analyses to reclassify this organism as a novel species, *M. marburgensis*, with strain Marburg as the type strain. Strain Marburg was isolated from mesophilic sewage sludge in Marburg, Germany, although other strains of this species may also be found in hot springs. Cells are slender, cylindrical rods, generally occurring in pairs or filaments up to 20 µm in length. Growth is autotrophic with H₂/CO₂ although when acetate is present it may be assimilated as cellular carbon (Wasserfallen et al., 2000).

METHANOTHERMOBACTER THERMOFLEXUS. This species was isolated from an

anaerobic sewage sludge digester and reported and described in 1993 (Kotelnikova et al., 1993). Cells are crooked rods frequently forming chains. The type strain is IDZ (DSM 7268).

METHANOTHERMOBACTER THERMOPHILUS. This organism was isolated from a thermophilic, anaerobic sewage sludge digester (Laurinavichus et al., 1987). Cells are slender, irregularly crooked rods frequently forming filaments up to 30 µm long. Unlike the other species of this genus, *M. thermophilus* requires coenzyme M for growth and is therefore not autotrophic. The type strain of this species is M (DSM 6529).

METHANOTHERMOBACTER WOLFEI. This species, originally described by Winter et al. (1984) as *Methanobacter wolfei*, is now recognized as a unique species of *Methanothermobacter* based upon phylogenetic data supporting its reclassification (Wasserfallen et al., 2000). Cells are generally rod-shaped although cultures of this organism may occur as cocci. This organism is autotrophic. It requires tungstate. The type strain is DSM 2970.

The Family Methanothermaceae

The family Methanothermaceae is represented by one genus, *Methanothermus*. Members of this family are very strict anaerobes and all grow by oxidizing H₂ to reduce CO₂ as the terminal electron acceptor. The species within *Methanothermus* have only been isolated from thermal springs with temperatures approaching 85°C at pH 6.5. Thus far it does not appear that these hyperthermophiles are widely distributed in thermal, anoxic habitats.

Methanothermus

The genus *Methanothermus* is represented by two species, *Methanothermus fervidus* and *Methanothermus sociabilis*.

METHANOTHERMUS FERVIDUS. This species, the type species of the genus *Methanothermus*, was isolated from an Icelandic hot spring and reported by Stetter et al. (1981). Subsequently, this species has only been detected in this particular system of thermal springs. Cells are slightly curved rods occurring singly and in short rod chains (Fig. 5). Unlike the majority of species within the order Methanobacteriales, this organism (as well as *M. sociabilis*) is motile via bipolar peritrichous flagella. This hyperthermophilic methanogen operates at an optimum temperature of 80–88°C by using H₂/CO₂ exclusively for growth and methanogenesis. The type strain is V24S (DSM 2088).

METHANOTHERMUS SOCIABILIS. This species, also isolated from an Icelandic solfatara,

Fig. 5. Electron micrograph of an ultrathin section of *Methanothermus fervidus*. Bar = 0.5 μ m. Courtesy of K.O. Stetter.

is the second species that has been found in the family Methanothermaceae (Lauerer et al., 1986). This species has not been detected outside of this collection of solfatara fields. The cells are rod-shaped and tend to grow in large clusters, which differentiates this species from *M. fervidus*. The optimal temperature supporting growth and methanogenesis on H_2/CO_2 is 88°C, and it can grow at temperatures up to ~97°C, as occurs for the other species of this genus. The lipid pattern within the cell wall is dissimilar to that of *M. fervidus*, further distinguishing the phenotypes of the two species. The type strain of this species is Kfl-F1 (DSM 3496).

The Order Methanosarcinales

MELISSA M. KENDALL AND DAVID R. BOONE

Introduction

Methanogens (methane-producing microbes) belong to the domain Archaea, and 16S rRNA gene sequences indicate that they form a phylogenetically distinct clade within the kingdom Euryarchaeota. The order Methanosarcinales is one of the five orders of methanogens. These microbes catalyze the terminal step in the degradation of organic matter in anoxic environments where light and terminal electron-acceptors other than CO₂ are limiting. Representatives of the Methanosarcinales are widespread and cosmopolitan in anaerobic environments. They are found in freshwater, marine environments, and extremely halophilic sediments as well as in anaerobic sludge digestors and the gastrointestinal tracts of animals. Use of molecular techniques has also identified Methanosarcinales in the deep terrestrial subsurface environments such as in the gold mines in South Africa.

Members of the order Methanosarcinales are coccoids, pseudosarcinae, or sheathed rods. Most cells have a protein cell wall, and some are surrounded by a sheath or acidic heteropolysaccharide; no peptidoglycan or pseudomurein is present. Hydroxyarchaeol is usually present in the lipids, which contain *myo*-inositol, ethanolamine and glycerol as polar headgroups. Cells are very strictly anaerobic and obtain energy with the concomitant production of methane. Methanosarcinales have the widest substrate range of methanogens: many can grow by reducing CO₂ with H₂, by dismutating methyl compounds, or by the splitting of acetate. Some species can use only one of those catabolic schemes, but others can use all three.

The order Methanosarcinales comprises two families, Methanosarcinaceae and Methanosarcinaceae. Some of their distinctive characteristics are listed in Table 1.

Habitats and Metabolism of Methanosarcinales

Similarly to other methanogens, Methanosarcinales are widespread in diverse anaerobic habi-

tats, including freshwater and marine mud and sediments, rumens of ungulates, animal waste lagoons, sludge from anaerobic sewage sludge digestors, and animal feces. Genetic sequences of 16S rRNA that are apparently from organisms that belong to Methanosarcinales have been detected in DNA from fissure water of deep South African gold mines (Takai et al., 2001), gas industry pipelines (Zhu et al., 2003), and a human periodontal pocket (Robichaux et al., 2003). In most natural environments where Methanosarcinales occur, they grow by splitting acetate to methane (CH₄) and carbon dioxide (CO₂), or they catabolize methyl compounds (methanol, methyl amines, methyl sulfides, etc.). In anoxic environments that lack light and alternate electron acceptors other than CO₂, methanogenesis is the major fate of organic matter that is degraded, and acetate splitting is the major source of methane. There are no other organisms than Methanosarcinales that are capable of catabolizing acetate in this manner. It is accomplished by members of one genus of the family Methanosarcinaceae (*Methanosarcina*) and by the only genus of the family Methanosarcinaceae (*Methanosarcina*). Acetate splitting is the sole catabolic pathway for this latter group.

The other important catabolic regime for Methanosarcinales is methanogenic catabolism of methyl groups. This catabolic pathway is accomplished by every known species of Methanosarcinaceae and is virtually exclusive to this family. (Members of the genus *Methanosphaera*, of the order Methanobacteriales, grow exclusively by reducing methanol with H₂.) Members of the genus *Methanosarcina* can dismutate methyl compounds such as methanol and methyl amines (sometimes methyl sulfides as well), producing one CO₂ and three CH₄ for each methyl compound dismutated. Most of these strains can also use H₂ to reduce methyl compounds when H₂ is also available. Other genera of Methanosarcinaceae lack the ability to use H₂. These genera occur in saline environments and probably acquire methyl compounds as degradation products of compatible solutes such as trimethylamine oxide, glycine betaine, or dimethylsulfoniopropionate.

Table 1. Some characteristics of the Methanobacteriales families.

Family	Characteristics
Methanobacteriaceae	Short lancet-shaped cocci, short-to-long rods, or filamentous rods; substrates for methanogenesis are $H_2 + CO_2$, formate and CO (which may also be oxidized), methanol (which may be reduced), and secondary alcohols + CO_2 ; cells typically stain Gram positive; nonmotile; little or no growth above $70^\circ C$; and G+C content, 23–61 mol%.
Methanothermaceae	Single rods and short rod chains; substrates for methanogenesis are $H_2 + CO_2$; stain Gram positive; motile; no growth below $60^\circ C$ and optimal growth generally above $70^\circ C$; and G+C content, 33 mol%.

The Methanosarcinales occur in anoxic sediments throughout the entire range of salinities, from anaerobic digestors and freshwater sediments to saturated brines. In low-salt environments, acetate and H_2 are the important methanogenic substrates. Although many Methanosarcinales can use H_2 to reduce CO_2 , they appear to be outcompeted for these substrates by other methanogens. But Methanosarcinales are entirely responsible for methanogenesis from acetate. All members of the genus *Methanosaeta* and most strains of *Methanosarcina* can grow on acetate. Strains of *Methanosaeta* have a lower K_m for acetate than do strains of *Methanosarcina*, so *Methanosaeta* often outcompete *Methanosarcina* in environments in which turnover is slow and acetate concentrations are low. *Methanosarcina* strains often predominate at lower pH values and when acetate concentrations are higher.

Members of the genus *Methanosaeta* are found in anaerobic digestors and sediments. The type strain of *Methanosaeta concilii* as well as several other strains of this species was isolated from anaerobic digestors (Patel, 1984; Ohtsubo et al., 1991), and *Methanosaeta thermophila* was isolated from mud in the thermal Khlodir Lake, in Kamchatka (Kamagata et al., 1992).

The genus *Methanosarcina* includes slightly halotolerant and slightly halophilic species. They are particularly common in anaerobic digestors. The type species of *Methanosarcina barkeri* as well as *Methanosarcina mazei*, *Methanosarcina vacuolata* and *Methanosarcina thermophila* was originally isolated from anaerobic sewage sludge digestors (Barker, 1936; Mah and Kuhn, 1984; Zinder et al., 1985; Bryant and Boone, 1987; Zhilina and Zavarzin, 1987b). Other species of this genus have been isolated from various sediment environments, including marine and estuarine sediments. Some of these marine species of *Methanosarcina* are methylotrophic (i.e., they grow by dismutating methyl compounds). *Methanosarcina acetivorans* was obtained from marine sediments (Sowers et al., 1984); *Methanosarcina baltica* was isolated from brackish sediments in the Gotland Deep of the Black Sea

(von Klein et al., 2002a); and *Methanosarcina semesiae* was isolated from mangrove sediment in Tanzania (Lyimo et al., 2000). *Methanosarcina lacustris* was isolated from freshwater anoxic lake sediments (Switzerland; Simankova et al., 2001), and *Methanosarcina siciliae* was obtained from sediments at the Lakes of Marinello, Italy (Ni and Boone, 1991; Ni et al., 1994). Additionally, another strain of *Methanosarcina siciliae*, strain C2J, was isolated from submarine canyon sediments near southern California (Elberson and Sowers, 1997). *Methanosarcina barkeri* strain CM1 has also been isolated from sheep rumen (Jarvis et al., 2000), although *Methanosarcina* do not occur commonly in rumen microflora.

Several genera of Methanosarcinaceae are slight halophiles, growing in environments with salinity near that of the ocean. These genera, including *Methanolobus*, *Methanococcoides* and *Methanosalsum*, are exclusively methylotrophic.

The major habitat of the genus *Methanolobus* is aquatic sediments. All current species were originally obtained from saline aquatic sediments. *Methanolobus tindarius* was isolated from seawater ponds near Tindari, Italy (König and Stetter, 1982). Two species have been isolated from marine sediments: *Methanolobus bombayensis* was isolated from Arabian Sea sediments near Bombay, India (Kadam et al., 1994), and *Methanolobus vulcanii* was isolated from submarine fumarole sediments near Vulcano Island, Italy (Stetter, 1989). *Methanolobus taylorii* was obtained from estuarine sediments from San Francisco Bay (Oremland and Boone, 1994). *Methanolobus oregonensis* was isolated from anoxic, subsurface sediments of a saline, alkaline aquifer near Alkali Lake, an alkaline, desert lake in south central Oregon (Liu et al., 1990).

The genus *Methanococcoides* contains two species, both from environments with salinity near that of seawater. *Methanococcoides methylutens* was isolated from submarine canyon sediments that contained large deposits of organic material off the coast of southern California (Sowers and Ferry, 1983), and *Methanococcoides burtonii* was obtained from the anoxic hypolim-

nion of Ace Lake, Anarctica (Franzmann et al., 1992).

The habitat of the genus *Methanosalsum* appears to be restricted to hypersaline soda lakes. *Methanosalsum zhilinae* was isolated from alkaline and saline sediments of a lake of the Wadi el Natrun in Egypt, and a second strain (strain Z-7936) was isolated from Lake Magadi, another alkaline soda lake (Mathrani et al., 1988).

Other Methanosarcinaceae are moderate halophiles, growing in hypersaline environments with Na⁺ concentration between about 1.0 M and 3.0 M. These, along with the extreme halophiles of the genus *Methanohalobium*, are also exclusively methylophilic.

Members of the genus *Methanohalophilus* have been isolated from diverse anoxic environments, in all cases with a salinity greater than that of seawater. *Methanohalophilus mahii* was obtained from the sediments of the Great Salt Lake (Paterek and Smith, 1985). *Methanohalophilus halophilus* was isolated from the ooze under a cyanobacterial mat and bottom deposits at Hamelin Pool, Shark Bay in Northwestern Australia (Zhilina, 1983; Zhilina and Kevrin, 1985; Wilharm et al., 1991), and *Methanohalophilus portucalensis* was retrieved from sediments of a solar salter in Figueira da Foz, Portugal (Boone et al., 1993). Saline subsurface water in an oil field yielded the culture "*Methanohalophilus euhalobius*" (Charakhchyan et al., 1989; Davidova et al., 1997).

Methanohalobium are generally found in extremely hypersaline environments. The type species, *Methanohalobium vestigatum*, was isolated from NaCl-saturated sediment of saline lagoons near Arabata, Sivash (Zhilina and Zavarzin, 1987a).

Cultivation

Methanosarcinales, like other methanogens, are strict anaerobes, and they must be cultivated by anaerobic techniques as described by Hungate (Hungate, 1969) or modifications of those techniques (Sowers and Noll, 1995). The use of serum tubes with butyl-rubber stoppers as culture vessels eliminates the difficulties in using pipets and mouth tubes, which require culture vessels to be opened anoxically for transfer of cultures. Modern techniques that use serum-stoppered vessels allow syringes to be used for inoculation. Culture fluid is transferred with syringes previously flushed with O₂-free gas.

Methanosarcinales are strict anaerobes, so culture medium must be prepared anoxically. Several types of media with various substrates will support the growth of Methanosarcinales.

A wide range of culture media are suitable for enriching, isolating, and cultivating these microbes. In this section, we describe culture media used by the Oregon Collection of Methanogens (Portland, Oregon, USA), which can be used to grow all of the methanogens described in this section.

Culture Media

The growth of very strictly anaerobic bacteria such as methanogens requires culture media that are completely free of O₂. The first description of methods to produce O₂-free culture media was provided by Hungate (1969), and several subsequent modifications have simplified the procedures for making medium (Sowers and Noll, 1995). One of the time-consuming procedures for preparing media for methanogens is boiling the water to remove O₂. In some laboratories, culture medium is successfully prepared without boiling the water or making any effort to remove O₂. We have found medium is more dependable when most of the O₂ is removed by flushing the liquid with O₂-free gas. We prepare bicarbonate buffer as the basal fluid for our medium by dissolving 0.1M NaOH or NaHCO₃ in water and equilibrating it with CO₂. When NaOH is added rather than NaHCO₃ it is important to equilibrate with CO₂ before adding minerals; otherwise precipitates may form. Alternately, the water can be boiled to remove oxygen and cooled under a gas phase containing CO₂. Then 100 mM sodium bicarbonate is added to establish the bicarbonate-CO₂ buffer.

The pH of this buffer when equilibrated with a gas phase of N₂ and CO₂ (7:3) is about 7.2 at 37°C, about 7.4 at 60°C, and about 7.15 at 4°C. Other pH values between about 6.6 and 8 can be achieved by adjusting the percentage of CO₂ in the gas phase. A gas phase of pure CO₂ (partial pressure of 1 atm) establishes the pH at about 6.6–6.7. Lower pH values can be achieved by adjusting with HCl before the vessels are sealed. After equilibration of the medium with a gas phase of N₂ and CO₂ (7:3), its pH can be adjusted to values higher than 7.2 by subsequently decreasing the CO₂ content of the gas. This should be done after autoclaving to prevent precipitation. Flushing culture medium with N₂ increases the pH to about 8. Higher pH values can be attained by adjusting with NaOH solution. Media are not strongly buffered by this system at pH values of about 8–8.6. At high pH values, the media described below may develop precipitates, such as apatites. These can be avoided by decreasing the concentration of phosphate or calcium. Also, at pH values above 8.5, ammonia toxicity is enhanced; it may be neces-

sary to reduce ammonia concentration to avoid this.

MS Medium (Boone et al., 1989)

NaOH	4.0 g
Yeast extract	2.0 g
Trypticase peptones	2.0 g
Mercaptoethanesulfonic acid	0.5 g
Na ₂ S · 9H ₂ O	0.25 g
NH ₄ Cl	1.0 g
K ₂ HPO ₄ · 3H ₂ O	0.4 g
MgCl ₂ · 6H ₂ O	1.0 g
CaCl ₂ · 2H ₂ O	0.4 g
Resazurin	1.0 mg
Sodium EDTA dihydrate	5.0 mg
CoCl ₂ · 6H ₂ O	1.5 mg
MnCl ₂ · 4H ₂ O	1.0 mg
FeSO ₄ · 7H ₂ O	1.0 mg
ZnCl	1.0 mg
AlCl ₂ · 6H ₂ O	0.4 mg
Na ₂ WO ₄ · 2H ₂ O	0.3 mg
CuCl ₂ · 2H ₂ O	0.2 mg
NiSO ₄ · 6H ₂ O	0.2 mg
H ₂ SeO ₃	0.1 mg
H ₃ BO ₃	0.1 mg
Na ₂ MoO ₄ · 2H ₂ O	0.1 mg

Dissolve the NaOH and equilibrate NaOH solution with CO₂ gas before its addition to the other ingredients. Dissolve all ingredients in gassed, distilled water and dilute up to 1 liter.

MH Medium (Boone et al., 1989)

MS medium	1.0 liter
NaCl	87.75 g
MgCl ₂ · 6H ₂ O	5.0 g
KCl	1.5 g

MSH Medium (Ni and Boone, 1991)

MS medium	2 parts
MH medium	1 part

MS, MSH or MH Mineral and Enrichment Media

Prepare MS mineral medium by adding all ingredients except the organic substrates such as yeast extract or trypticase peptone. Additionally, prepare an enrichment medium containing reduced concentrations of yeast extract and trypticase peptone (i.e., 0.5 g of each per liter) and increased concentration of sulfide (i.e., 0.5 g per liter; Ni and Boone, 1991). In these enrichment media, eliminate the mercaptoethane sulfonate to prevent the enrichment of bacteria that decompose this compound, and reduce yeast extract and peptone concentrations to limit the growth of heterotrophs while still providing the nutrients needed by methanogens for their growth. Prepare MS, MSH, or MH mineral and enrichment media by following the changes described below.

Enrichment cultures of *Methanosarcina* may be initiated in one of the enrichment media

described above, with salinity and pH adjusted to match the environment of the sample. A catabolic substrate such as acetate (50–100 mM), methanol (30 mM), or methylamines (mono-, di- or trimethylamine; 30 mM) should be added. Organic growth factors that are required by some strains are provided by the yeast extract and peptones of the enrichment medium. For rapid enrichment of *Methanosarcina*, trimethylamine is the preferred substrate. Acetate may be the most selective substrate for the isolation of *Methanosarcina*, especially when the pH of the medium is lower than 7.0, but growth is slower than on trimethylamine, and not all species of this genus can catabolize acetate.

Methanolobus may be enriched in MSH medium to which trimethylamine or methanol has been added as catabolic substrate. For the growth of *Methanolobus bombayensis*, 1.7 g of KCl should be added per liter of medium.

Cultures of *Methanococcoides* can also be enriched with MSH medium to which trimethylamine has been added as catabolic substrate. When grown in a defined mineral medium, *Methanococcoides methylutens* requires biotin (Sowers and Ferry, 1985a). *Methanococcoides burtonii* can be enriched with MSH enrichment medium with trimethylamine by incubating at 15°C (Franzmann, 1992).

All *Methanohalophilus* may be enriched in MH medium with 20 mM trimethylamine as catabolic substrate.

Methanosalsum may be cultivated by using MSH culture medium (pH 8–9.5) containing methylamines or methanol as catabolic substrate.

The growth of *Methanohalobium* requires higher salt concentrations than those provided in MH medium. *Methanohalobium* can be grown by increasing the NaCl concentration from 1.5 M to 3 M. No organic substrates are required for growth. Yeast extract is inhibitory at 500 mg/liter, but at concentrations of 50–100 mg/liter, yeast extract can replace vitamins in the medium.

Species of *Methanosaeta* can be enriched in MS mineral medium containing acetate as the main organic source of carbon and energy for growth. *Methanosaeta thermophila* can be grown in MS medium with a final concentration of 10% MSH medium added. Vitamins should be added to the culture medium, as some strains of *Methanosaeta* require and others may be stimulated by vitamins. Yeast extract may be inhibitory to these organisms, so it should be omitted from the medium. *Methanosaeta* species are generally out-competed by faster growing, acetate-utilizing *Methanosarcina* species, which can cause problems in their isolation. Janssen has suggested starting with batch enrichment cultures in which acetone and isopropanol are used as growth sub-

strates for the enrichment step. These substrates are slowly fermented by certain bacteria to acetate, which then allows the *Methanosaeta* species to maintain acetate concentration at levels below the threshold required for growth of *Methanosarcina* species. This can result in dense populations of *Methanosaeta* which can subsequently be separated from contaminating microbes to yield pure cultures (Janssen, 2003).

Maintenance

Cultures of *Methanosarcina*, *Methanohalophilus* and *Methanosalsum* may be maintained by regular subculturing as described by Hippe (1984). Strains of *Methanococcoides* are maintained by transfer every 3 months on agar slants or in liquid medium stored at room temperature (or at lower temperatures for *Methanococcoides burtonii*) in the dark. For longer term storage, cultures can be maintained by freezing in liquid growth medium and glycerol (3:1 [v/v]; Tumbula et al., 1995). Cultures stored in this fashion have remained viable for 10 years. Cultures of *Methanohalophilus* can survive weeks or months after growth by storing cultures at room temperature in the dark, as long as the culture remains anoxic. Working cultures of *Methanosaeta* can be maintained by transfer into appropriate broth media at regular intervals of 1–4 weeks, depending on the strain. Often large inocula (10–50%) are required to initiate growth.

All species of *Methanosarcinales* can be stored as frozen stocks; 5% glycerol is added as a cryoprotectant before cell suspensions are anoxically distributed into vials, slowly frozen at a rate of 1°C/min to –40°C, and then stored at liquid nitrogen temperatures (Boone, 1995).

The Family Methanosarcinaceae

Methanosarcinaceae includes six genera of coccoidal or pseudosarcinal bacteria. Most cells have a protein cell wall. Other cells are surrounded by an acidic heteropolysaccharide. No cells contain peptidoglycan or pseudomurein. The lipids contain *myo*-inositol, ethanolamine and glycerol as polar head groups. All strains can gain energy by dismutating methyl compounds. The use of acetate or CO₂ reduction with H₂ may be observed; however, no strains catabolize formate.

Methanosarcina

The genus *Methanosarcina* comprises nine species: *Methanosarcina barkeri* (Fig. 1), *Methanosarcina acetivorans*, *Methanosarcina sicilae*

Fig. 1. Thin section of aggregates of *Methanosarcina barkeri*. Courtesy of Henry Aldrich, Department of Microbiology and Cell Science, University of Florida, Gainesville, FL.

Fig. 2. Electron micrograph of *Methanosarcina sicilae*. Courtesy of Henry Aldrich, Department of Microbiology and Cell Science, University of Florida, Gainesville, FL.

(Fig. 2), *Methanosarcina thermophila* (Fig. 3), *Methanosarcina mazei* (Fig. 4), *Methanosarcina vacuolata*, *Methanosarcina baltica*, *Methanosarcina lacustris* and *Methanosarcina semesiae*. All strains are nonmotile and can catabolize acetate, methanol, methylamines and CO. Some strains are able to gain energy by the reduction of CO₂ with H₂. Refer to Tables 2–5 for further information about these species' phenotypic and physiological characteristics.

Symbols and abbreviations: +, growth; –, no growth; V, vitamins; AA, amino acids; YE, yeast extract; P, peptones; PABA, *p*-aminobenzoate; B, biotin; Th, thiamine; RF, rumen fluid; SF, sludge fluid; CA, casamino acids; and nd, not determined.

The original type strain of *Methanosarcina barkeri*, isolated by Schnell (1947), has been lost. In 1966, Bryant isolated strain MS (Bryant and Boone, 1987), which has been adopted as the neotype strain, and this strain is one of the most extensively studied methanogens. Additional information on *Methanosarcina barkeri* can be found in Scherer and Bochem (1983) and Maestrojuán and Boone (1991).

Certain strains may dechlorinate chloroform. For example, *Methanosarcina* sp. strain DCM and *Methanosarcina mazei* S-6 catalyze this reaction; however, ¹⁴CO₂ is formed rather than ¹⁴CH₄. This suggests that the mechanism is not reductive (Mikesell and Boyd, 1990), but other data suggest that dechlorination is reductive (Holliger et al., 1992).

Methanobrevibacter

The genus *Methanobrevibacter* is represented by five species with coccoidal morphology, *Methanobrevibacter tindarus*, *Methanobrevibacter bombayensis*, *Methanobrevibacter oregonensis* (Fig. 5), *Methanobrevibacter taylorii* and *Methanobrevibacter vulcani*. All cells are

surrounded by a unit membrane and a protein S-layer. Cells may grow on methanol, methylamines, and sometimes on methyl sulfides; no strains can grow on H₂/CO₂, formate, acetate or alcohols (other than methanol). For further descriptive information about each strain, see Tables 2–5.

Methanococcoides

The genus *Methanococcoides* comprises two species, *Methanococcoides methylutens* (Figs. 6 and 7) and *Methanococcoides burtonii*. Cells are irregular cocci, and the cell wall consists of a very thin protein monolayer approximately 10-nm thick. Cells can dismutate methylamines and methanol for growth but cannot catabolize acetate, dimethylsulfide, H₂/CO₂ or formate. Refer to Tables 2–5 for further descriptive information.

Methanohalobium

The genus *Methanohalobium* contains a single species, *Methanohalobium evestigatum*. This

Fig. 5. A) Electron micrograph of *Methanohalophilus oregonense* cells. B) Single cell of *Methanohalophilus oregonense*. Courtesy of Henry Aldrich, Department of Microbiology and Cell Science, University of Florida, Gainesville, FL.

Fig. 6. Phase-contrast photomicrograph of *Methanococcoides methylutens*. Bar = 10 μ m. Courtesy of K. Sowers, Center for Marine Biotechnology, University of Maryland Biotechnology Institute, Baltimore, MD.

Fig. 7. Thin-section transmission electron photomicrograph of *Methanococcoides methylutens* stained with uranyl acetate. Bar = 1 μ m. Courtesy of K. Sowers, Center for Marine Biotechnology, University of Maryland Biotechnology Institute, Baltimore, MD.

species is extremely halophilic and moderately thermophilic. Substrates for growth include methylamines but not acetate, formate, or H_2/CO_2 . Methanol may be catabolized at very low concentrations (<5 mM) but not at concentrations of 20 mM or greater (Zhilina and Zavarzin, 1987a; Boone et al., 1993). The type strain of this species requires B-vitamins or yeast extract for growth. Tables 2–5 provide more descriptive information.

Methanohalophilus

This genus comprises three species, *Methanohalophilus mahii*, *Methanohalophilus halophilus* and *Methanohalophilus portucalensis*. Cells multiply by constriction of cell into two daughter cells rather than by fission. Cells are nonmotile. Cells grow on methylamines and methanol; however, methanol is toxic at concentrations of 40 mM or above. Cells do not grow on secondary alcohols, acetate, formate or H_2/CO_2 . The addition of yeast extract and trypticase peptones to culture media at a concentration of 0.05% inhibits growth. Tables 2–5 describe further phe-

notypic and physiological characteristics of these organisms.

Methanosalsum

Methanosalsum zhilinae is the sole species in this genus. The cell wall is an S-layer. Energy and methane production are possible when this strain is grown on methylamines, methanol or dimethylsulfides but not on acetate, formate or H_2/CO_2 (Boone et al., 1986; Mathrani et al., 1988; Kadam and Boone, 1996; Kevbrin et al., 1997). Dimethylsulfide at 20 mM or greater concentration inhibits methane production (Mathrani et al., 1988). Refer to Tables 2–5 for more information about this organism.

The Family Methanosaetaceae

The family Methanosaetaceae includes one genus, *Methanosaeta*. Lipids are composed of *myo*-inositol and ethanolamine, with galactose in the polar head groups. All cells utilize acetate as the sole energy source.

Fig. 8. *Methanosaeta concilli* culture observed under phase contrast microscopy. Bar = 5 μ m. Courtesy of Girish Patel, National Research Council of Canada, Institute for Biological Sciences, Ottawa, Canada.

The genus *Methanosaeta* is represented by two species, *Methanosaeta concilli* (Fig. 8) and *Methanosaeta thermophila*. Both organisms split acetate into methane and CO₂, and acetate is the sole energy substrate. Tables 2–5 further describe phenotypic and physiological characteristics of these organisms.

Originally, aceticlastic, rod-shaped methanogens were described within the genus *Methanotherix*, with *Methanotherix soehngenii* strain Opfikon as the type species and strain, respectively. However, the first description of this genus and its type species was based on a culture that probably was not pure, thus the genus *Methanotherix* was later considered illegitimate. A pure culture of aceticlastic, mesophilic, rod-shaped methanogens was described by Patel (Patel, 1984; Patel, 1985) as *Methanotherix concilli*, with strain GP6 as the type strain for this species. Patel later transferred the species *Methanotherix concilli* to a new genus, *Methanosaeta*, with *Methanosaeta concilli* as the type species and strain GP6 as the type strain for this species. Comparisons between strain GP6 and strain Opfikon revealed that these two organisms most likely were subjective synonyms. Responding to a Request for Opinion (Boone, 1991), the Judicial Commission of the International Committee on Systematic Bacteriology denied the request to assign strain GP6 as a neotype for *Methanotherix soehngenii* (Wayne, 1994), which reaffirmed strain GP6 as the type strain of *Methanosaeta concilli*. *Methanotherix soehngenii* is now widely considered to be illegitimate because its description was not based on a pure culture.

Additionally, the first descriptions of thermophilic rod-shaped aceticlastic methanogens, *Methanotherix thermophila*, most likely were based on impure cultures (Nozhevnikova and Chudina, 1985; Zinder et al., 1987). It has recently been proposed that *Methanotherix thermophila* be transferred to the genus *Methanosaeta* as *Methanosaeta thermophila* comb. nov. Boone and Kamagata (1998) have submitted a Request for Opinion to reject the species *Methanotherix* as *nomina confusa* and to place these two names on the list of rejected names. On the basis of this proposal, thermophilic strains originally validly described as *Methanotherix thermophila* (Kamagata et al., 1992) are presented in this chapter as *Methanosaeta thermophila*. Only the descriptions of aceticlastic, rod-shaped, sheathed methanogens that have been based on pure cultures have been included in this chapter. Thus, to date, *Methanosaeta* includes two species, *Methanosaeta concilli* and *Methanosaeta thermophila*.

Methanococcales

WILLIAM B. WHITMAN AND CHRISTIAN JEANTHON

Phylogeny

The sequencing of representative genes of the methane-producing archaea in the order Methanococcales suggests that this lineage is ancient and possesses a high degree of genetic diversity. For example, the mesophile *Methanococcus maripaludis* and hyperthermophile *Methanocaldococcus jannaschii* represent the range of diversity within this group. The sequence similarity of their 16S rRNA genes is 88%. Likewise, homologous open reading frames in these two organisms typically possess 60–80% amino acid sequence identity (W. B. Whitman, unpublished observation). For comparison, genes within *Escherichia* and *Yersinia* possess a comparable level of similarity.

In spite of this apparent genetic diversity, the phenotypes of members of the Methanococcales are similar. They have all been isolated from marine habitats and require sea salts for optimal growth. They are all obligately anaerobic methane-producers and use carbon dioxide as the electron acceptor. Hydrogen and sometimes formate are electron donors. Acetate, C-1 compounds such as methanol and methylamines, and alcohols such as isopropanol and ethanol are not utilized as substrates for methanogenesis. They are all irregular cocci with a diameter of 1–3 μm . The cell wall is composed of a protein S-layer, and glycoproteins and cell wall carbohydrates have not been detected. Cells are usually motile by means of flagellar tufts or bundles. However, there is tremendous diversity in the temperature range for growth, which varies from mesophilic to hyperthermophilic. Within each of these temperature ranges, these organisms are among the fastest growing methanogens known, with generation times of 2 hours at 37°C and less than 30 minutes at 85°C. Lastly, many of the Methanococcales require selenium for optimal growth.

Currently, the Methanococcales have been divided into two families and four genera on the basis in part of the temperature optima for growth (Table 1). For the most part this taxon-

omy reflects the apparent phylogeny of the 16S rRNA gene, but there are some points of ambiguity (Keswani et al., 1996). The two hyperthermophilic genera *Methanocaldococcus* and *Methanotorris* are placed in the family Methanocaldococcaceae, and this grouping appears robust (Fig. 1). It has strong bootstrap support, and it is found by more than one algorithm including the Fitch-Margoliash, neighbor-joining, and maximum likelihood analyses. However, the differences in mol% G+C content of the rRNAs of the hyperthermophiles and mesophiles within this group can bias these computations (Burggraf et al., 1990). When the phylogenetic analyses are performed with only transversions, which ameliorates this bias, the mesophiles appear as a sister group to the hyperthermophile *Methanotorris*, and the Methanocaldococcaceae are no longer a phylogenetic group. To resolve this question, the phylogeny of additional genes should be examined.

Similarly, within the Methanococcaceae, the mesophiles are assigned to the genus *Methanococcus* and the thermophiles to the genus *Methanothermococcus* (Whitman et al., 2001). Within the *Methanococcus*, the deepest phylogenetic group is represented by the patent strain “*Mc. aeolicus*” (Fig. 1). However, upon phylogenetic analyses of the rRNA gene, this strain forms a clade with the thermophile *Methanothermococcus okinawensis* (Takai et al., 2002; Fig. 1). This clade is also supported by transversion analysis. Even though bootstrap support is modest, the common alternative topologies found during the bootstrap analysis do not group the mesophiles to the exclusion of the thermophiles. Although phylogenetic analyses of other molecules are needed to confirm this result, it implies that the genera *Methanococcus* and *Methanothermococcus* are so deeply branched that they include distantly related and phenotypically dissimilar organisms. A taxonomic treatment more consistent with the phylogeny would probably place “*Mc. aeolicus*” and *Mtc. okinawensis* into two novel genera.

Table 1. Taxa in the order Methanococcales^a

Family	Genus	Species
Methanococcaceae	<i>Methanococcus</i> ^T	“ <i>aeolicus</i> ” <i>maripaludis</i> <i>voltae</i> <i>vannielii</i> ^T
	<i>Methanothermococcus</i>	<i>okinawensis</i> <i>thermolithotrophicus</i> ^T
Methanocaldococcaceae	<i>Methanocaldococcus</i> ^T	<i>fervens</i> <i>infernus</i> <i>jannaschii</i> ^T <i>vulcanius</i>
	<i>Methanotorris</i>	<i>igneus</i> ^T

^aNomenclatural types are indicated with a superscript “T.” Species that have not been validated are in quotes.

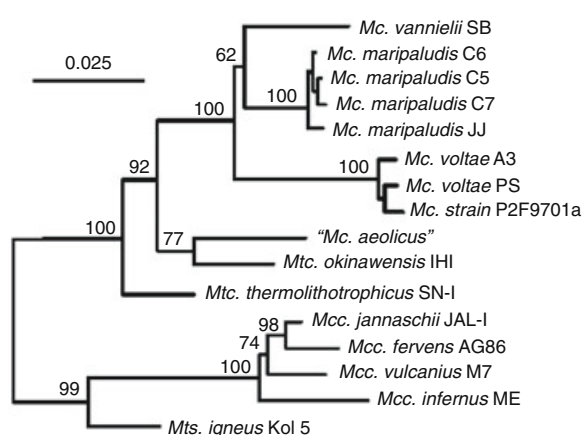

Fig. 1. Phylogeny of the 16S rRNA gene of the *Methanococcales*. The alignment was manually edited to include 1227 positions of unambiguous alignment. Evolutionary distances were calculated by the Kimura two-parameter model, and the tree was constructed by the Fitch-Margoliash algorithm in PHYLIP (phylogenetic analysis package). Bootstrap analysis was performed with 100 replicates, and values greater than 50 are reported on the nodes. Mc. = *Methanococcus*, Mtc. = *Methanothermococcus*, Mts. = *Methanotorris*, and Mcc. = *Methanocaldococcus*. The scale bar represents evolutionary distance.

Taxonomy

An overview of the current taxonomy of the Methanococcales is given in Table 1. This taxonomy groups organisms with similar temperature optima. All the mesophiles and thermophiles are found within the family Methanococcaceae. The mesophiles are assigned to the genus *Methanococcus* and the thermophiles to the genus *Methanothermococcus*. For the hyperthermophiles, two genera, *Methanocaldococcus* and *Methanotorris* are recognized within the family Methanocaldococcaceae. Although this taxonomy is in general agreement with the phylogeny of the rRNA, some ambiguity remains. To resolve these issues, additional strains and the phylogenies of

other molecules will probably be required (see above).

Historically, the genus *Methanococcus* included methane-producing cocci that did not form regular packets (i.e., *Methanosarcina*) or chains (i.e., some species of *Methanobacterium*, now *Methanobrevibacter*; Bryant, 1974). At that time, the type species, *Methanococcus mazei*, was not available in pure culture, and only one other species, *M. vannielii*, was known. Upon analysis of the partial sequence of the 16S rRNAs of methanogens (Balch et al., 1979) and isolation of an archaeon with the phenotype of *M. mazei* (Mah, 1980), it became apparent that *M. mazei* was related to the Methanosarcinaceae and that *M. vannielii* was related to a new species, *Methanococcus voltae*. Thus, it was proposed that *M. vannielii* become the new type species for the genus and *M. mazei* be reclassified as *Methanosarcina mazei* (Balch et al., 1979; Mah and Kuhn, 1984; Judicial Commission, 1986). Likewise, species more closely resembling *M. mazei* were placed in the Methanosarcinaceae. Thus, *Methanococcus halophilus*, which utilizes methylamines for methane synthesis, was not classified with the Methanococcaceae (Zhilina, 1983). Similarly, *Methanococcus frisius* resembles *Methanosarcina mazei* by nutritional and morphological criteria (Blotvogel et al., 1986) and was also classified with the Methanosarcinaceae.

Although the remaining methanococcal species were more closely related to each other than other methane-producing bacteria, they were not a closely knit group (Whitman, 1989). In particular, the sequence of the 16S rRNA of *M. jannaschii* was different enough from the other methanococci to justify creation of a new genus (Jones et al., 1983a). The eventual isolation of additional hyperthermophilic methanococci and the sequencing of the 16S rRNAs of most of the methanococci led to the recommendation that the genus be further subdivided into four genera to reduce the genetic diversity (Boone et al.,

1993). This proposal left the mesophilic species in the genus *Methanococcus* and placed the thermophiles and hyperthermophiles in novel genera. The 16S rRNA sequence similarities (>91%) and DNA hybridizations (>3%) among the remaining, mesophilic species were still somewhat lower than those found in many other bacterial and archaeal genera, suggesting that this group was still rather diverse (Keswani et al., 1996). However, in the absence of additional species, there seemed to be little benefit in subdividing this genus at this time.

The more moderate thermophiles, with 16S rRNA sequence similarities of <91% to the mesophiles as well as the hyperthermophiles, were placed in the new genus *Methanothermococcus*. The hyperthermophiles, which possessed <86% rRNA sequence similarity to the mesophiles, were placed in two new genera, *Methanocaldococcus* and *Methanotorris* (originally called "*Methanoignis*," see below). Members of these new genera possessed low 16S rRNA sequence similarity (<93%) to each other as well as differences in nutritional and other phenotypic properties. Within the genus *Methanocaldococcus*, the 16S rRNA sequence similarity was greater than 95%. The genus name "*Methanotorris*" was proposed to replace the original name "*Methanoignis*," which was incorrectly formed (Whitman et al., 2001). The correct latinization was "*Methanignis*." Therefore, *Methanotorris* was proposed to preserve the prefix "*methano*-" in the genus name.

The present descriptions of some of the methanococci are based on the description of a single isolate. Therefore, the known phenotypic characteristics may not be truly representative of the species. For instance, the growth responses of strains of *Methanococcus maripaludis* to NaCl and MgCl₂ are variable, and care must be taken when making taxonomic distinctions on this basis (Whitman et al., 1986). More reliable and rapid comparison of strain collections can be made by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of cellular proteins and restriction fragment length polymorphism (RFLP) analyses of the 16S rRNA (Keswani et al., 1996; Jeanthon et al., 1999a).

Habitat

To date, methanococci have only been isolated from marine environments. *Methanococcus vanielii* was isolated from the shore of the San Francisco Bay (Stadtman and Barker, 1951). The type strain of *M. voltae* was isolated from sediments from the mouth of the Waccasassa River estuary in Florida (Ward, 1970). The type strain of *M. maripaludis* was isolated from salt-marsh

sediments near Pawley's Island, South Carolina (Jones et al., 1983b). Additional strains of *M. voltae* and *M. maripaludis* have been isolated from salt-marsh sediments in Georgia and Florida and an estuary in Taiwan (Whitman et al., 1986; Keswani et al., 1996; Lai and Shih, 2001). An unnamed methanococcal isolate has also been obtained from the biofilm of a ship hull (Boopathy and Daniels, 1992).

Methanothermococci have been isolated from coastal geothermally heated marine sediments at Stufe di Nerone near Naples (Italy; Huber et al., 1982) and reservoir water from a North Sea oil field (Nilsen and Torsvik, 1996). A new *Methanothermococcus* species (*M. okinawaensis*) has been recently isolated from a deep-sea hydrothermal vent of the Okinawa Trough (Pacific Ocean; Takai et al., 2002). Environmental clone sequences closely related to this genus have also been obtained from continental high-temperature oil reservoirs (Orphan et al., 2000).

Methanocaldococci are widespread in deep submarine hydrothermal systems. *Methanocaldococcus* species have so far been isolated from chimney material of deep-sea hydrothermal vents at the East Pacific Rise (13°N and 21°N; Jones et al., 1983a; Jeanthon et al., 1999a) and Mid-Atlantic Ridge (14°45'N and 23°N; Jeanthon et al., 1998; Jeanthon et al., 1999a) and hydrothermally heated sediment from Guaymas Basin (Gulf of California; Zhao et al., 1988; Jones et al., 1989; Jeanthon et al., 1999a). Environmental clone sequences closely related to this genus have also been retrieved from hot formation waters of a continental oil reservoir in western Siberia (Nercessian et al., 2000).

Methanotorris was originally isolated from sediments and venting water of a shallow submarine hydrothermal vent at Kolbeinsey Ridge located on the Mid-Atlantic Ridge (north of Iceland; Burggraf et al., 1990). Fifteen additional strains have been isolated from sediments from a Guaymas Basin hydrothermal site (Gulf of California) and chimney samples from the Mid-Atlantic Ridge (23°N; Jeanthon et al., 1999a).

Isolation

The Methanococcales, like other methane-producing archaea, are strict anaerobes that require specialized techniques for their cultivation. This methodology has been reviewed recently by Sowers and Noll (1995) and will not be discussed here. The mesophilic methanococci may be easily isolated after enrichment under H₂ + CO₂ (80:20) in pressurized tubes or bottles (Miller and Wolin, 1974; Balch and Wolfe, 1976). Because of their rapid growth, methanococci frequently outgrow other H₂-utilizing metha-

nogens in marine sediments. Therefore, this enrichment is somewhat specific, and enrichment cultures that take longer than 5 days to develop seldom contain methanococci. The enrichments are transferred to medium containing antibiotics (penicillin G [0.2 mg/ml], erythromycin [0.2 mg/ml] and streptomycin sulfate [0.2 mg/ml]) before plating on agar plates or roll tubes (Jones et al., 1983b; Jones et al., 1983c; Tumbula et al., 1995a). In some cases, it is necessary to include antibiotics in the solid medium to prevent growth of spreading bacteria over colonies of methanococci. Isolated colonies are picked with a syringe needle and transferred to liquid medium. Purity may be demonstrated by microscopic examination, restreaking on agar medium and absence of growth in mineral medium supplemented with 1% casamino acids and glucose under $N_2 + CO_2$ (80:20).

A useful medium for isolation and rapid growth of methanococci consists of:

Glass distilled water	500 ml
General salts solution	500 ml
K_2HPO_4 solution	10 ml
Trace mineral solution	10 ml
Iron stock solution	5 ml
Resazurin solution	1 ml
NaCl solution	75 ml
$NaHCO_3$	5 g

The concentrations of stock K_2HPO_4 , NaCl, and resazurin solutions are 14 g/liter, 293 g/liter and 0.1 g/100 ml of glass distilled water, respectively. The iron stock solution is prepared by adding 0.2 g of $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$ to a small bottle, adding 2 drops of concentrated HCl followed by 100 ml of glass distilled water. This solution is prepared fresh monthly. The oxygen indicator resazurin is optional. These components are combined, and the medium is brought to a boil under a stream of $N_2 + CO_2$ (80:20). After boiling, cysteine or 2-mercaptoethanesulfonate, 0.5 g/liter, is added to reduce the medium. When hot, the medium will form a precipitate that goes back into solution upon cooling. After dispensing the medium anaerobically into crimp seal tubes or serum bottles, the gas is exchanged for $H_2 + CO_2$ (80:20, 100 kPa), and the medium sterilized by autoclaving. The medium may then be stored for several months in an anaerobic chamber (Coy Laboratories, Ann Arbor, Michigan). Within one day of inoculation, one part of sterile 2.5% $Na_2S \cdot 9H_2O$ (w/v) is added to 50 parts of medium. After inoculation, the tubes are pressurized to 200 kPa with $H_2 + CO_2$. Tubes are repressurized periodically throughout growth. During the period of rapid growth immediately following the lag phase, cultures need to be repressurized 3–4 times per day. If the CO_2 in the headspace is allowed to become too low, the pH of the medium will rise. Under alkaline conditions, the cells lyse (Schauer and Whitman, 1989). For growth in vessels that will not maintain a pressure >100 kPa, the $NaHCO_3$ concentration is reduced to 2 g/liter.

For *M. voltae*, the mineral medium must be supplemented with either yeast extract, 2 g/liter, or sodium acetate $\cdot 3H_2O$, 0.14 g/liter, L-

isoleucine, 0.5 g/liter, L-leucine, 0.5 g/liter, and pantoyllactone, 1.3 mg/liter (Whitman et al., 1986). Similarly, the addition of casamino acids (2 g/liter) and sodium acetate $\cdot 3H_2O$ (0.14 g/liter) is stimulatory for *M. maripaludis*.

General Salts Solution (modified from Romesser et al., 1979)

KCl	0.67 g
$MgSO_4 \cdot 7H_2O$	6.9 g
$MgCl_2 \cdot 6H_2O$	5.5 g
NH_4Cl	1.0 g
$CaCl_2 \cdot 2H_2O$	0.28 g
Glass distilled water	1000 ml

Trace Metal Solution (modified from Wolfe's minerals; Balch et al., 1979)

Nitilotriacetic acid, neutralized with KOH	1.5 g
$MnSO_4 \cdot 2H_2O$	0.1 g
$Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$	0.2 g
$CoCl_2 \cdot 6H_2O$	0.1 g
$ZnSO_4 \cdot 7H_2O$	0.1 g
$CuSO_4 \cdot 5H_2O$	10 mg
$NiCl_2 \cdot 6H_2O$	25 mg
Na_2SeO_3	0.2 g
$Na_2MoO_4 \cdot 2H_2O$	0.1 g
$Na_2WO_4 \cdot 2H_2O$	0.1 g

Sodium Sulfide Solution

A pellet of NaOH is added to 100 ml of distilled water, and the water is brought to a boil under a stream of N_2 gas and allowed to cool under N_2 in the fume hood. Then a large crystal of about 2.5 g of $Na_2S \cdot 9H_2O$ is briefly washed in a 25-ml beaker of distilled water. The crystal is blotted dry on a paper towel, reweighed and added to the NaOH solution. Because sulfide is toxic, chemically impermeable gloves are worn, and this procedure is performed in the fume hood. The solution is stoppered, brought into the anaerobic chamber, and dispensed into tubes and stoppered. The tubes are pressurized to 100 kPa with N_2 , autoclaved, and stored in the anaerobic chamber for up to one month.

Methanothermococci and methanocaldococci may be isolated after enrichment under H_2/CO_2 (80:20, 200 kPa) in 50- or 100-ml serum bottles (Jeanthon et al., 1998).

Methanothermococci-Methanocaldococci Culture Medium

Sea salts (Sigma)	30 g
NH_4Cl	1 g
KH_2PO_4	0.35 g
PIPES	3.46 g
$NaHCO_3$	1 g
Difco yeast extract	2 g
Cysteine $\cdot HCl$	0.5 g
Na_2SeO_4	0.5 mg
$Na_2WO_4 \cdot 2H_2O$	2 mg
Vitamin B_{12}	0.05 mg
Trace element mixture (see below)	1 ml
Vitamin mixture (see below)	1 ml
Thiamine solution (see below)	1 ml
Growth-stimulating factors (see below)	1 ml
Resazurin	1 mg
Distilled water	1000 ml

Trace Element Mixture (Widdel and Bak, 1992)

HCl (25% = 7.7 M)	12.5 ml
FeSO ₄ · 7H ₂ O	2.1 g
H ₃ BO ₃	30 mg
MnCl ₂ · 4H ₂ O	100 mg
CoCl ₂ · 6H ₂ O	190 mg
NiCl ₂ · 6H ₂ O	24 mg
CuCl ₂ · 2H ₂ O	2 mg
ZnSO ₄ · 7H ₂ O	144 mg
Na ₂ MoO ₄ · 2H ₂ O	36 mg
Distilled water	987 ml

The solution is autoclaved under a N₂ (100%) atmosphere in serum bottles closed with tightly fitting rubber stoppers and fixed with aluminum seals.

Vitamin Mixture (Widdel and Bak, 1992)

Sodium phosphate buffer (10 mM; pH 7.1)	100 ml
4-Aminobenzoic acid	4 mg
D(+)-Biotin	1 mg
Nicotinic acid	10 mg
Calcium D(+)-pantothenate	5 mg
Pyridoxine dihydrochloride	15 mg

The solution is filter-sterilized (pore size, 0.2 µm) and kept in the dark at 4°C under a N₂ atmosphere (100 kPa).

Thiamine Solution (Widdel and Bak, 1992)

Ten mg of thiamine chloride dihydrochloride is dissolved in 100 ml of 25 mM sodium phosphate buffer, pH 3.4. The solution is filter-sterilized and kept at 4°C under a N₂ atmosphere (100 kPa).

Growth-stimulating Factors Solution (Pfennig et al., 1981)

Isobutyric acid	0.5 g
Valeric acid	0.5 g
2-Methyl-butyric acid	0.5 g
3-Methyl-butyric acid	0.5 g
Caproic acid	0.2 g
Succinic acid	0.6 g
Distilled water	100 ml

The solution, adjusted to pH 9 with NaOH, is autoclaved under a N₂ (100%) atmosphere in serum bottles closed with tightly fitting rubber stoppers and fixed with aluminum seals.

The pH of the Methanothermococci-Methanocaldococci culture medium is adjusted to 6.5 using 1 M HCl before autoclaving, and the medium is reduced by adding sodium sulfide Na₂S · 9H₂O to a final concentration of 0.05% (w/v). Solid medium is prepared by the addition of 0.7% (w/v) Phytigel (Sigma Chemical, Co., St. Louis, MO) and reduced with a titanium (III) citrate solution (Zehnder and Wuhrman, 1976). For methanothermococci, agar (2%, w/v) can be used as gelling agent. Medium is dispensed into Petri dishes in an anaerobic glove box. Plates are incubated at 60°C (for methanothermococci) or at 75°C (for methanocaldococci) in anaerobic jars for 3–5 days under a H₂/CO₂ atmosphere (80:20; 250 kPa).

Identification

To identify the mesophilic *Methanococcus* spp., isolates must be first distinguished from a num-

ber of morphologically and nutritionally similar species of *Methanogenium* and *Methanoculleus* that are also present in marine environments (Romesser et al., 1979; Rivard and Smith, 1982; Ferguson and Mah, 1983; Rivard et al., 1983). Methanococci may be distinguished from these other species by their faster growth rate, requirement for higher concentrations of NaCl for optimal growth, lack of organic growth requirements (except *M. voltae*) and the lower mol% G+C of their DNA. Unlike some members of these other genera, the methanococci have not been found to use secondary alcohols or ethanol as electron donors for methanogenesis. However, identification of isolates based solely on morphological and growth characteristics is equivocal, and use of salt or mineral requirements has been particularly deceptive (see below). Thus, antigenic crossreactivity (Conway de Macario et al., 1981) and 16S rRNA sequencing (Keswani et al., 1996) are helpful for final identification of new isolates.

Strains of methanococci may also be rapidly screened by one-dimensional SDS-PAGE of cellular proteins (Whitman, 1989; Keswani et al., 1996). Cultures are grown to an absorbance of 1.0 cm⁻¹ at 600 nm, and 5-ml cultures are harvested by centrifugation. The cells are resuspended in 0.1 ml of mineral medium or a salt solution prepared without reducing agents. This cell suspension may be stored at -20°C prior to electrophoresis. After thawing, the suspension is vortexed to form an even suspension, and 15 µl are added to 60 µl of sample buffer containing sodium dodecyl sulfate and 2-mercaptoethanol. A portion, 35 µl, of this mixture is subjected to electrophoresis on a 12% polyacrylamide gel. The protein profile on SDS-PAGE is sufficiently distinctive to distinguish species of mesophilic methanococci from each other or from other methanogenic bacteria like *Methanogenium* species (data not shown).

Methanothermococcus is distinguished from the mesophile *Methanococcus* and the hyperthermophiles *Methanocaldococcus* and *Methanotorris* by its moderate thermophily. It differs from most other moderately thermophilic methanogens (such as *Methanothermobacter*) by its coccoid morphology. So far, *Methanoculleus thermophilicum* is the only other moderately thermophilic coccus described (Rivard and Smith, 1982; Ferguson and Mah, 1983). *Methanoculleus thermophilicum* requires acetate for growth, grows in low concentrations of NaCl, has a mol% G+C of 56–60, and is easily distinguished by these properties. Antigenic crossreactivity (Conway de Macario et al., 1981; Bryniok and Trosch, 1989; Nilsen and Torsvik, 1996), 16S rRNA sequencing (Keswani et al., 1996), and SDS-PAGE of cellular proteins (Nilsen and

Fig. 2. Restriction patterns of 16S rRNA genes of the type strains of hyperthermophilic methanococci and isolates from deep-sea hydrothermal vents selectively amplified and digested with *Bst*UI. The marker is a 100-bp ladder. From Jeanthon et al. (1999a), and used with permission of the publisher.

Torsvik, 1996) are also helpful for final identification of new isolates.

Methanocaldococcus and *Methanotorris* are distinguished from the mesophile *Methanococcus* and the thermophile *Methanothermococcus* by their hyperthermophily. The hyperthermophiles may be distinguished from each other because *Methanocaldococcus* requires selenium for optimal growth and possesses flagellar tufts. Restriction fragment length polymorphism (RFLP) of the gene encoding the 16S rRNA has proven useful for distinguishing species of *Methanocaldococcus* from each other as well as from strains of *Methanotorris* and *Methanothermococcus* (Jeanthon et al., 1999a). Distinctive RFLP patterns are obtained after restriction of the amplified 16S rRNAs of the species of the three genera with *Hha*I, *Msp*I and *Bst*UI endonucleases (Fig. 2). The profiles obtained with *Hae*III show distinctive patterns for all the type strains except for *M. jannaschii* and *M. fervens*. It is difficult to distinguish species of *Methanocaldococcus* on phenotypic properties alone. Of the four species currently described, only *M. fervens* is resistant to rifampicin, and only *M. jannaschii* is not stimulated by yeast extract.

A number of compounds have also proven to be useful chemotaxonomic markers. The core lipids of *Methanococcus* are composed of archaeol and hydroxyarchaeol (Koga et al., 1998). In *Methanothermococcus*, caldarchaeol is also present. In *Methanocaldococcus* and *Methanotorris*, hydroxyarchaeol is absent and a cyclic derivative of archaeol is found. In all four genera, the polar head groups are composed of glucose, *N*-acetylglucosamine, serine and ethanolamine (in some species). The most abundant polyamine is spermidine in *Methanococcus* and *Methanothermococcus* (Kneifel et al., 1986; Hamana et al., 1998). Spermine is the most

abundant polyamine in *Methanocaldococcus*. Unusual compatible solutes have not been detected in *Methanococcus* spp. In *Methanothermococcus*, β -glutamate and *N*-acetyl- β -lysine are abundant, depending on the growth condition (Robertson et al., 1990; Robertson et al., 1992). In *Methanocaldococcus*, β -glutamate is the most abundant compatible solute. *Methanotorris* contains di-*myo*-inositol-1,1'-phosphate in addition to β -glutamate (Ciulla et al., 1994).

Preservation

Because the methanococci lyse shortly after the cessation of growth in liquid media, stock cultures are grown below the temperature optimum (30°C) and stored at room temperature for up to 3 weeks. Strains of all the mesophilic methanococci have been stored with little loss in viability for up to 3 years in 25% glycerol at -70°C (Whitman et al., 1986; Tumbula et al., 1995b). Cultures 10 years or older have been routinely revived. Tube cultures are first concentrated by centrifugation and resuspended in a one-fifth volume of medium containing yeast extract and 25% glycerol (v/v). Portions of the cell suspension are transferred to sterile 1-ml screw-top glass vials in an anaerobic chamber. The vials are then stored at -70°C without anaerobic precautions. To revive the cultures, 0.2 ml of the cell suspension are allowed to thaw in an anaerobic chamber and transferred to fresh medium. Methanococci have also been stored by freeze-drying (Hippe, 1984) and freezing in glycerol (Winter, 1983).

For long-term preservation of the methanothermococci, strains are grown in suspension overnight, repressurized, and stored at 4°C, after which these suspensions can serve as an inoculum for at least 6 months. Using the same procedure, *Methanothermococcus thermolithotrophicus* strain ST22, stored at room temperature, was viable for at least 2 years (Nilsen and Torsvik, 1996). Cultures can also be stored at -80°C in fresh culture medium containing 20% (w/v) glycerol.

Characteristics of Methanococcales

Methanococcus

The genus *Methanococcus* is represented by four species whose properties are summarized in Table 2. Growth occurs at mesophilic temperatures, with the optima near 35–40°C. The pH optima for growth are between 6 and 8. During balanced growth, cells are slightly irregular and uniform in size, between 1 and 2 μ m in diameter (Fig. 3). Pairs of cells are common. In stationary

Table 2. Descriptive characteristics of the species of the genus *Methanococcus*.

Characteristic	<i>vannielii</i>	<i>voltae</i>	<i>maripaludis</i>	" <i>aeolicus</i> "
Irregular coccus	+	+	+	+
Cell diameter, μm	1.3	1.3–1.7	0.9–1.3	1.7

^aOf the type strain.

^bBecause this species has not been formally described, this strain is not a nomenclatural type.

Fig. 3. *Methanococcus voltae* showing the polar flagellar tuft. The cells were negatively stained with 1% phosphotungstate (pH 7) and viewed with a JEOL 1200EX transmission electron microscope at 80 kV. (Electron micrograph courtesy of Shin-Ichi Aizawa and Ken Jarrell.)

cultures, colonies or enrichment cultures, cell shape is very irregular, and large cells up to 10 μm in diameter are observed (Jones et al., 1977b). In wet mounts, a few cells in a preparation may slowly swell and burst (Ward, 1970). Cells on the edge of a slide where drying may occur are much larger, less irregular, and more transparent than cells from the center of the slide. Cells from older cultures are mechanically

fragile and rupture during vigorous stirring or upon harvesting by some continuous centrifugation devices. Cells are also osmotically fragile, and they lyse rapidly in distilled water. Cell integrity is maintained in 2% NaCl (w/v). Cells lyse rapidly in 0.01% sodium dodecyl sulfate (SDS) and contain a protein cell wall or S-layer. In *M. vannielii* and *M. voltae*, the outer cell surface is composed of hexagonally ordered structures (Jarrell and Koval, 1989). Cells are motile, and *M. vannielii* contains two tufts or bundles of flagella at the same pole.

Methanococcus spp. are obligate anaerobes and obligate methanogens. Molecular hydrogen (H_2) and formate serve as electron donors. Acetate, methanol and methylamines are not substrates for methanogenesis. All the strains tested are unable to utilize alcohols such as ethanol, isopropanol, isobutanol and cyclohexanol as electron donors for CO_2 reduction (Zellner and Winter, 1987). While an unnamed isolate of *Methanococcus* has also been reported to utilize methylfurfural compounds as a substrate for methanogenesis, the only strain of *Methanococcus maripaludis* tested did not utilize methylfurfural (Boopathy, 1996).

Except for *M. voltae*, the methanococci will grow in mineral medium with sulfide as the sole reducing agent and carbon dioxide as the sole carbon source (Whitman et al., 1986). Autotrophic CO_2 fixation is by the modified Ljungdahl-Wood pathway of acetyl-CoA biosynthesis (Shieh and Whitman, 1987; Shieh and Whitman, 1988; Ladapo and Whitman, 1990).

Methanococcus maripaludis is a facultative autotroph, and acetate and amino acids are stimulatory to growth. The amino acids are incorporated into cellular protein with a high efficiency but not further metabolized (Whitman et al., 1987). In contrast, the growth of *M. vannielii* and "*M. aeolicus*" is not affected by acetate or amino acids. *Methanococcus voltae* requires acetate, isoleucine and leucine for growth (Whitman et al., 1982). Isovalerate and 2-methylbutyrate can substitute for leucine and isoleucine, respectively. Pantoyllactone and pantoic acid, which are formed from pantothenate during autoclaving, can also stimulate growth. These requirements are the same for the type strain as well as other strains isolated from the coastal regions in the southeastern United States (Whitman et al., 1986). However, a strain isolated from Taiwan does not possess an absolute requirement for acetate or amino acids, although acetate and tryptone are stimulatory (Lai and Shih, 2001). The reason for this discrepancy is not known. Since DNA hybridization was not performed, it is possible that this strain may represent a novel but closely related species. Alternatively, the difference in growth responses may be due to different growth conditions employed in different laboratories, or the growth requirements may not be a characteristic of all members of the species. Glycogen has been identified as a storage product in most methanococci (König et al., 1985; Yu et al., 1994).

Nitrogen sources for the methanococci include ammonium, N₂ gas and alanine. Ammonium is sufficient as a nitrogen source for all methanococci and is required by *M. voltae* even during growth with amino acids (Whitman et al., 1982). Molecular nitrogen (N₂ gas) and alanine are additional nitrogen sources for *M. maripaludis*. *Methanococcus vannielii* cannot utilize N₂ gas or amino acids as nitrogen sources, but it will utilize purines (DeMoll and Tsai, 1986; Whitman, 1989).

Sulfide is sufficient as a sulfur source for all methanococci. Elemental sulfur is also reduced to sulfide (Stetter and Gaag, 1983; W. B. Whitman, unpublished data). Cysteine, dithiothreitol and sulfate do not substitute for sulfide (Whitman et al., 1982; Whitman et al., 1987). Some strains of *M. maripaludis* utilize thiosulfate as a sulfur source (Rajagopal and Daniels, 1986).

In addition to NaCl, high concentrations of magnesium salts are stimulatory or required by the methanococci (Whitman et al., 1982; Whitman et al., 1986; Corder et al., 1983; Jones et al., 1983b). Calcium is required by *M. voltae* (Whitman et al., 1982). Selenium is stimulatory to all species tested (Jones and Stadtman, 1977a; Whitman et al., 1982; Jones et al., 1983b). Iron, nickel and cobalt are required or stimulatory for

M. voltae (Whitman et al., 1982), and tungsten and nickel are required or stimulatory for *M. vannielii* (Jones and Stadtman, 1977a; Diekert et al., 1981).

Like other archaea, methanococci are generally resistant to low concentrations of many common antibiotics (Jones et al., 1977b). Some antibiotics that are inhibitory at low concentrations are: adriamycin, chloramphenicol, efrapeptin, leucinostatin, metonidazole, monensin, pleuromutilin, pyrrolnitrin and virginiamycin (Elhardt and Böck, 1982; Böck and Kandler, 1985). Methanococci are also sensitive to low concentrations of organic tin-containing compounds such as: phenyltin, tripropyltin and triethyltin (Boopathy and Daniels, 1991).

METHANOCOCCUS AEOLICUS This irregular coccus has an average diameter of 1.7 µm and occurs singly or in pairs. For growth, the temperature range is ≥20–45°C, the pH range is 6.5–8.0, the range of NaCl concentration is 1→5%, and the optimum is 1–2%. Ammonium and N₂ can serve as sole nitrogen sources, and selenium but not acetate or amino acids stimulates growth. Cells are susceptible to lysis by 0.01% sodium dodecyl sulfate (SDS) and hypotonic solutions. The mol% G+C is 32.0 (liquid chromatography method [LC]). The type strain has not been designated, and this taxon is currently represented solely by a patent strain (Schmid et al., 1984; Keswani et al., 1996; Whitman, 2001).

METHANOCOCCUS DELTAE Although validly published, this species is a subjective synonym of *M. maripaludis*. Hence, it is not further described here (Corder et al., 1983; Keswani et al., 1996).

METHANOCOCCUS MARIPALUDIS This irregular coccus has an average diameter of 0.9–1.3 µm and occurs singly or in pairs. For growth, the temperature range is ≥20–45°C, the pH range is 6.5–8.0, the range of NaCl concentration is 0.3–5%, and the optimum is 0.6–2%. Ammonium, alanine and N₂ can serve as sole nitrogen sources. Selenium, acetate and amino acids are stimulatory for growth. Cells are susceptible to lysis by 0.01% SDS and hypotonic solutions. The mol% G+C is 33–35 (LC). The type strain is JJ (= DSMZ 2067 = OCM 175; Jones et al., 1983b; Keswani et al., 1996; Whitman, 2001).

METHANOCOCCUS VANNIELII Cells are irregular cocci, with an average diameter of 1.3 µm, and occur singly or in pairs. For growth, the temperature range is ≥20–45°C, the pH range is 6.5–8.0, the range of NaCl is 0.3–5%, and the optimum is 0.6–2%. Ammonium and purines, but not alanine and N₂, can serve as sole nitrogen sources. Selenium stimulates growth, whereas acetate

and amino acids do not. Cells are susceptible to lysis by 0.01% SDS and hypotonic solutions. The mol% G+C is 32.5 (LC). *Methanococcus vanielii* is the type species of the genus. The type strain is SB (= ATCC 35089 = DSMZ 1224 = OCM 148; Stadtman and Barker, 1951; Whitman, 2001).

METHANOCOCCUS VOLTAE Cells are irregular cocci, with an average diameter of 1.3–1.7 μm , and occur singly or in pairs. For growth, the temperature range is ≥ 20 –45°C, the pH range is 6.5–8.0, the range of NaCl is 0.3–5%, and the optimum is 1–2%. Ammonium but not alanine and N_2 can serve as sole nitrogen source. Selenium is stimulatory for growth. Acetate and amino acids leucine and isoleucine are required or greatly stimulate growth. Cells are susceptible to lysis by 0.01% SDS and hypotonic solutions. The mol% G+C is 29–32 (LC). The type strain is PS (= ATCC 33273 = DSMZ 1537 = OCM 70; Ward, 1970; Whitman, 2001).

Methanothermococcus

The genus *Methanothermococcus* is represented by two species, *Methanothermococcus thermolithotrophicus* and *M. okinawensis*, whose properties are summarized in Table 3. In both cases, cells are Gram-negative irregular cocci and motile by means of a polar tuft of flagella. They lyse immediately in distilled water and in the presence of dilute solutions of SDS. They are thermophilic, with a temperature optimum of 60–70°C. NaCl is required for growth. They grow autotrophically in defined mineral medium with

H_2 and CO_2 . H_2 and formate are used as electron donors for methanogenesis. Acetate, methanol, and methylamines are not substrates for methane production. Organic carbon sources are not stimulatory for growth. The mol% G+C is 31–32. The type species is *M. thermolithotrophicus*.

METHANOTHERMOCOCCUS OKINAWENSIS These irregular cocci have an average diameter of 1.0–1.5 μm and occur singly or in pairs. They are vigorously motile by means of a polar bundle of flagella. For growth, the temperature range is 40–70°C, the optimum is 60–65°C, the pH range is 4.5–8.5, optimum is 6–7, the concentration of sea salts is 1.2–9.6%, and the optimum is 2.0–5.0%. Ammonium is the nitrogen source, and selenium and magnetite (Fe_3O_4) are stimulatory for growth. Cells are susceptible to lysis by 0.1% SDS and hypotonic solutions. This species was first isolated from a deep-sea hydrothermal vent chimney at the Iheya Ridge, in the Okinawa Trough. The type strain of the species is IH 1 (= JCM11175 = DSM 14208; Takai et al., 2002).

METHANOTHERMOCOCCUS THERMOLITHOTROPHICUS

Cells are regular to irregular cocci (diameter, 1.5 μm) that occur singly or in pairs. On agar and in Gelrite, round yellowish colonies around 1 mm in diameter are formed. About 20 flagella are inserted at a distinct area on the cell surface. The cells lyse immediately in the presence of 2% SDS; the cell envelope consists of protein subunits. Their optimum temperature for growth is 60–65°C (range, 17–70°C); optimum pH, 6–7.5 (range, 4.9–9.8); and optimum NaCl concentration, 1.8–4% (range, 0.6–9.4%). Methane is

formed from H_2/CO_2 and from formate. Organic material does not stimulate growth. Both N_2 and nitrate can serve as sole nitrogen sources (Belay et al., 1984; Belay et al., 1990). Sulfur is reduced to hydrogen sulfide with inhibition of methanogenesis. The DNA base composition is 31–32 mol% G+C. It is the type species of the genus *Methanothermococcus*. Type strain of the species is strain SN1^T (= DSM2095 = ATCC35097 = JCM10549 = OCM 138). The species was first isolated from the sandy geothermally heated sediment of a beach at Stufe di Nerone close to Naples (Italy; Huber et al., 1982; Nilsen and Torsvik, 1996).

Methanocaldococcus

Genus *Methanocaldococcus* is composed of four species (Table 4). Cells are irregular cocci motile by means of polar tufts of flagella and readily lyse in distilled water and in the presence of dilute solutions of SDS. The genus is hyperthermophilic (optimum temperature for growth, 80–85°C). NaCl is required for growth. Cells grow autotrophically in defined mineral medium with H_2 and CO_2 . Formate, acetate, methanol, and methylamines are not substrates for methane production. Selenium and tungsten are stimulatory for growth. The G+C content is 31–33 mol%. It is the type genus of the family Methanocaldococcaceae. The type species of the genus is *M. jannaschii*.

METHANOCALDOCOCCLUS FERVENS These regular to irregular cocci (diameter, 1–2 μm) occur singly and in pairs, and form whitish, translucent, and round colonies about 0.5 mm in diameter on Gelrite plates. Their optimum temperature for growth is 85°C (range, 48–92°C); optimum pH, 6.5 (range, 5.5–7.6); and optimum NaCl concentration, 3% (range, 0.5–5%). Yeast extract, casamino acids, and trypticase are stimulatory for growth. DNA base composition is 33 mol% G+C (thermal denaturation method). The type strain is AG86^T (= DSM4213). The species was first isolated from a deep-sea hydrothermal vent core sample from Guaymas Basin, Gulf of California, at a depth of 2,003 m (Jeanthon et al., 1999b).

METHANOCALDOCOCCLUS INFERNUS These irregular cocci (diameter, 1–3 μm) occur singly and in pairs. Cells exhibit a tumbling motility by means of at least three tufts of flagella. The cell envelope consists of a hexagonally arranged S-layer with a lattice constant of 12.2 nm (Fig. 4). Pale yellow colonies about 1 mm in diameter form on “Phytigel” plates. Optimum temperature for growth is 85°C (range, 55–91°C); optimum pH, 6.5 (range, 5.25–7.0); and optimum NaCl concentration, 2% (range, 0.8–3.5). Yeast extract is stimulatory for growth. Elemental sulfur is reduced to hydrogen sulfide in the presence of CO_2 and H_2 . DNA base composition is 33 mol% G+C (thermal denaturation method). The type strain

is strain ME^T (= DSM11812). The species was first isolated from a deep-sea hydrothermal vent chimney in the Mid-Atlantic Ridge (14°45'N; Jeanthon et al., 1998).

METHANOCALDOCOCCLUS JANNASCHII These irregular cocci measure 1.5 µm in diameter and occur singly or in pairs. The cell surface is composed of hexagonally ordered substructures; two bundles of flagella are inserted close to the same cell pole. Colonies are convex, circular, yellowish in color with a smooth shiny surface. Optimum temperature for growth is 85°C (range, 50–91°C); optimum pH, 6.0 (5.2–7.0); and optimum NaCl concentration, 3%. Acetate, formate, yeast extract, trypticase, and vitamins are not stimulatory for growth. Sulfide is required. DNA base composition is 31 mol% G+C (buoyant density method). The species was first isolated from sedimentary material at the base of a white smoker submarine hydrothermal vent (21°N at 2,600-m depth on the East Pacific Rise). It is the type species of the genus *Methanocaldococcus*. The type strain is strain JAL-1^T (= DSM 2661 = ATCC 43067 = JCM 10045 = OCM 168; Jones et al., 1983a; Jeanthon et al., 1999a).

METHANOCALDOCOCCLUS VULCANIUS These irregular cocci (diameter, 1–3 µm) occur singly and in pairs. Cells exhibit a tumbling motility by means of three tufts of flagella (Fig. 5). Pale yellow round colonies about 1 mm in diameter form on

“Phytigel” plates. Optimum temperature for growth is 80°C (range, 49–89°C); optimum pH, 6.5 (range, 5.25–7); and optimum NaCl concentration, 2.5% (range, 0.6–5.6%). Yeast extract is stimulatory for growth. Sulfur is reduced to hydrogen sulfide in the presence of CO₂ and H₂. DNA base composition is 31 mol% G+C (thermal denaturation method). The type strain is M7^T (= DSM 12094 = ATCC700851). The species was first isolated from a deep-sea hydrothermal vent chimney on the East Pacific Rise (13°N; Jeanthon et al., 1999b).

Methanotorris

Genus *Methanotorris* is represented by a single hyperthermophilic species, *Methanotorris igneus*.

METHANOTORRIS IGNEUS This irregular coccus (diameter, 1.3–1.8 µm) occurs singly and in pairs. Cells are nonmotile, and no tufts of flagella are visible; a few flagella-like filaments are visible on some cells. Pale yellow round smooth colonies are formed on agar. Optimum temperature for growth is 88°C (range, 45–91°C); optimum pH, 5.7 (range, 5–7.5); optimum NaCl, 1.8% (range, 0.45–7.2%). Cells form methane from H₂ and CO₂. Selenium is not required for growth and selenium, yeast extract and peptone are not stimulatory for growth. Formate, acetate, methanol, and methylamines are not substrates for methane production. Sulfur is reduced to hydrogen

sulfide in the presence of CO₂ and H₂. DNA base composition is 31 mol% G+C (thermal denaturation method). It is the type species of the genus *Methanotorrus*. The type strain is Kol5^T (= DSM5666). The species was first isolated from a shallow submarine hydrothermal vent system at the Kolbeinsey Ridge (Mid-Atlantic Ridge north of Iceland, at a depth of 106 m; Burggraf et al., 1990; Jeanthon et al., 1999a).

Biochemical and Physiological Properties

Genomic Sequence

Methanocaldococcus jannaschii was the first archaeon and hyperthermophile whose genome was sequenced, and it has served as model for other hyperthermophiles and archaea (Bult et al., 1996). While a review of the genome exceeds the scope of this review, an updated annotation that summarizes many of the recent advances is available (Graham et al., 2001). The genomic sequence has also been used to reconstruct the metabolism of this autotroph (Selkov et al., 1997).

Flagellum and Motility

Although the appearance is similar, the flagella of the methanococci and other archaea are very different from those of bacteria (for recent reviews, see Faguy and Jarrell, 1999; Jarrell et al., 1996, and Thomas et al., 2001a). The flagellum itself is somewhat narrower, about 10–14 nm, than bacterial flagella, which are >20 nm. The conspicuous hook and basal structure common on bacterial flagella is not observed; instead, a hook without the basal structure is usually seen (Fig. 6). In some studies, a simple basal body has also been visualized. The archaeal flagellins have sequence similarity to the bacterial type IV pilins and not the bacterial flagellins. They are also biosynthesized with a leader peptide, which implies different mechanisms of assembly and transport across the membrane than are found with the bacterial flagella. Thus, the archaeal and bacterial structures do not appear to be homologous. In support of this conclusion, homologs of genes encoding the bacterial flagellins, basal body and motility apparatus are not found in archaeal genomes.

Effects of Pressure on Thermophilic Methanogens

Methanocaldococcus jannaschii was the first hyperthermophilic organism isolated from deep-sea hydrothermal vents. Owing to the depth of

Fig. 6. Flagella of *Methanococcus voltae*. A hook region similar to that found on bacterial flagella is present on the flagella from methanococci. While a basal body has not been observed in these preparations, it is possible that the bodies are present in the cells but lost upon purification. Whole cells were concentrated and solubilized with 1% of the detergent OP-10 in the presence of DNase and RNase. Following removal of the membranes by centrifugation, the flagella were precipitated using 2% polyethylene glycol and 100 mM NaCl. The flagella were then further purified on a KBr gradient. (Electron micrograph courtesy of Shin-Ichi Aizawa and Ken Jarrell.)

these vents, the in situ pressure is generally between 20 and 30 MPa (hydrostatic pressure increases by about 10 MPa or 100 atm for every kilometer of seawater). *Methanocaldococcus jannaschii* has therefore served as a model for the effects of pressure on the growth and metabolism of deep-sea thermophiles and for comparison with organisms isolated from the surface at low pressure (i.e., *M. thermolithotrophicus*). High hyperbaric pressures of helium (up to 75 MPa) increase the growth rate of *M. jannaschii* at 86 and 90°C but do not to extend its upper temperature limit for growth (Miller et al., 1988). However, increased pressures extend the upper temperature limit for methanogenesis from less than 94°C at 0.78 MPa to 98°C at 25 MPa. In contrast, following growth at 50 MPa, cells of *M. thermolithotrophicus* are anomalously large and elongated, and the cellular amino acid composition and protein pattern are dramatically changed (Jaenicke et al., 1988). Its growth rate is also enhanced without extending its temperature range (Bernhardt et al., 1988).

Understanding the mechanisms that stabilize proteins, especially at extreme temperatures, is a challenging problem in both biochemistry and biotechnology. The initial findings raised the question of how pressure could extend the thermal stability of thermophilic enzymes. Hei and Clark (1994) compared the pressure effect on the thermal stability of a partially purified hydrogenase from *M. jannaschii* to that from *M. igneus*, *M. thermolithotrophicus* and *M. maripaludis*, all isolated from shallow marine sites. Application of 50 MPa increased the thermal half-life of hydrogenase from *M. jannaschii* 4.8-fold at 90°C. Since hydrogenase from the other hyperthermophile, *M. igneus*, was also substantially stabilized by pressure whereas the hydrogenases from *M. thermolithotrophicus* and *M. maripaludis* were destabilized by pressure, it was suggested that pressure stabilization of enzymes was related to their thermophilicity. In further studies, the thermostability of a protease from *M. jannaschii* also increased at high pressure (Michels and Clark, 1997). However, the destabilization by pressure of the adenylate kinase from *M. jannaschii* demonstrated that hyperbaric stabilization was not an intrinsic property of all enzymes from deep-sea thermophiles (Konisky et al., 1995). In studying the pressure effects on lipids from *M. jannaschii*, Kaneshiro and Clark (1995) showed that pressure had a lipid-ordering effect over the full range of growth temperatures for this organism. The shift toward macrocyclic archaeol from archaeol and caldarchaeol was shown to decrease membrane fluidity.

Genetics

Genetic systems have been utilized extensively in the mesophiles *Methanococcus voltae* and *M. maripaludis* (for a review, see Tumbula and Whitman, 1999). Methods that have become available include efficient transformation systems; antibiotic resistance markers for puromycin and neomycin; reporter genes such as those for β -galactosidase, β -glucuronidase and trehalase; and shuttle and expression vectors. Evidence for a phage transduction system has also been described for *M. voltae* strain PS (Bertani, 1999). This system depends upon VTA (or *voltae* transfer agent) and allows for low frequencies of genetic exchange with a wide variety of markers. The VTA appears to be a small polyhedral phage that carries 4.4-kb fragments of circular DNA that are derived from the host genome (Eiserling et al., 1999). This phage-like particle is similar to the gene transfer agent described for *Rhodobacter capsulata* but different from another

phage discovered in *M. voltae* strain A3 (Wood et al., 1985).

Genetic methods have been utilized to examine the expression of the hydrogenase and motility genes of *M. voltae* and the nitrogen fixation genes of *M. maripaludis*. *Methanococcus voltae* contains two sets of hydrogenase genes. One set encodes the selenium-dependent enzymes that contain selenocysteine residues at the active site. The second set encodes the selenium-free enzymes. Both sets include both the coenzyme F₄₂₀-reducing and coenzyme F₄₂₀-independent hydrogenases (reviewed in Sorgenfrei et al., 1997). The genes encoding the selenium-free enzymes are divergently transcribed from a 453-bp intergenic region that contains the *cis* elements for transcriptional regulation. Expression is only observed in the absence of selenium in the growth medium and appears to be both negatively and positively regulated. Negative regulation results from a silencer region in the middle of the intergenic region (Noll et al., 1999). Positive regulation results from binding of a transcriptional activator immediately upstream of both promoters (Müller and Klein, 2001).

The flagellar biosynthetic genes have been extensively studied in *M. voltae* (reviewed in Thomas et al., 2001a). These genes are arranged into two transcriptional units. The first unit encodes only *flaA*, one of the four flagellin genes present. The second unit encodes the remaining three flagellin genes as well as a number of other genes whose functions are not fully known. Homologs to these other genes are found in the motility gene clusters of other archaea, so they are probably required for flagellar assembly or motility. Although the functions of these genes are not known, mutants with an insertional inactivation of at least one of these genes are no longer flagellated (Thomas et al., 2001b). This experiment provides direct evidence for a role in motility.

Methanococcus maripaludis fixes nitrogen, and the regulation of the *nif* operon, which encodes the nitrogenase genes as well as other genes important for nitrogen fixation, has been studied in detail (for a review, see Leigh, 1999). Expression of the *nif* operon is under control of a repressor (Cohen-Kupiec et al., 1997). In addition, cellular nitrogenase activity is further regulated by two GlnB homologs. In various bacteria, GlnB homologs posttranslationally regulate the activity of a number of key enzymes in nitrogen assimilation, including nitrogenase and glutamine synthetase. Although the specific mechanism is not known, the methanococcal GlnB homologs are responsible for the rapid and reversible “switching off” of nitrogenase activity (Kessler et al., 2001).

Nanoarchaeota

HARALD HUBER, MICHAEL J. HOHN, REINHARD RACHEL AND KARL O. STETTER

Introduction

All cultivated *Archaea* known so far belong to one of two phyla, *Crenarchaeota* or *Euryarchaeota* (Woese et al., 1990). The *Crenarchaeota* are composed of three orders, Desulfurococcales (Huber et al., 2001), Sulfolobales and Thermoproteales (Burggraf et al., 1997; Garrity and Holt, 2001a). The *Euryarchaeota* harbor different orders of methanogenic and halophilic microorganisms, sulfate reducers (Archaeoglobales), Thermoplasmatales, and Thermococcales (Garrity and Holt, 2001b). In addition, several years ago, a third archaeal phylum was proposed, the so-called “*Korarchaeota*” (Barns et al., 1996). However, this group is only indicated by 16S rDNA sequences obtained from environmental DNAs and still nothing is known of the corresponding organisms. In contrast, a novel phylum named “*Nanoarchaeota*” was described recently by Huber et al. (2002), which is represented by a nano-sized hyperthermophilic symbiont that grows attached to the surface of a new *Ignicoccus* species. “*Nanoarchaeum equitans*,” the first representative of this phylum, was obtained from a sample of submarine hot rocks taken at the Kolbeinsey Ridge, north of Iceland, from a water depth of 106 m (Huber et al., 2002). It has a cell diameter of only 400 nm and grows under strictly anaerobic conditions at temperatures between 75 and 98°C. Molecular investigations revealed that “*Nanoarchaeum equitans*” harbors a highly divergent 16S rDNA sequence which exhibits several base exchanges even in previously “universal” sequence signatures (= primer sequences). In addition, several environmental 16S rDNA sequences from high temperature biotopes have been obtained which also belong to representatives of this phylum (Hohn et al., 2002).

Phylogeny

On the basis of 16S rDNA sequence comparisons, the phylum “*Nanoarchaeota*” represents an isolated deep lineage within the *Archaea* (Fig. 1). It forms a separate cluster and is distinct from the three other phyla, the *Crenarchaeota*, *Eur-*

yarchaeota and the “*Korarchaeota*.” “*Nanoarchaeum equitans*” and three other 16S rRNA sequences representing this phylum (LPC33, OP9, and CU1) exhibit phylogenetic similarities between 83 and 100% (Hohn et al., 2002). The sequence from the East Pacific Rise (LPC33) was identical to the sequence of “*Nanoarchaeum equitans*,” while the others had previously unknown primary structures. In agreement with this, the three sequences consistently grouped together in phylogenetic analyses with high bootstrap support (98–100%), regardless of the dataset or phylogenetic algorithm used (distance matrix: neighbor joining; Fitch-Margoliash algorithm; maximum parsimony; or maximum-likelihood (fastDNAm1) methods; Ludwig and Strunk, 2001). In comparison to all other archaeal species, the phylogenetic similarities were between 67 and 80% (Hohn et al., 2002). These values indicate that the phylum is well defined by 16S rRNA gene sequence comparisons, as expressed in the corresponding phylogenetic trees (Fig. 1). In all phylogenetic analyses, the “*Nanoarchaeota*” branch off very deeply within the archaeal domain. The placement of the “*Nanoarchaeota*” branch within the *Archaea*, however, is problematic. Their position varies significantly, depending on the analytical method used and the domain-specific filter sets applied. Also, in all calculations, very low (and therefore insignificant) bootstrap values are obtained for the branching point of the “*Nanoarchaeota*” lineage. Therefore, the definite branching position for the “*Nanoarchaeota*” is unclear at the moment. Possibly, additional organisms and/or sequences of this novel lineage may stabilize the 16S rRNA-based trees.

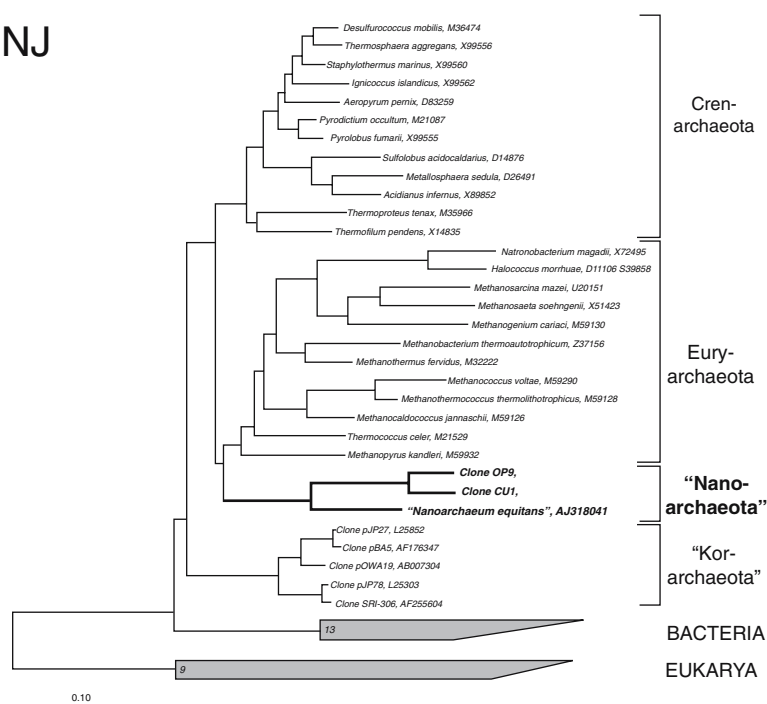

Phylogenetic investigations based on analyses of the 23S rRNA sequence of “*Nanoarchaeum equitans*” resulted in similar tree topologies and were consistent with the 16S rRNA trees (M. J. Hohn and H. Huber, unpublished observation).

Taxonomy

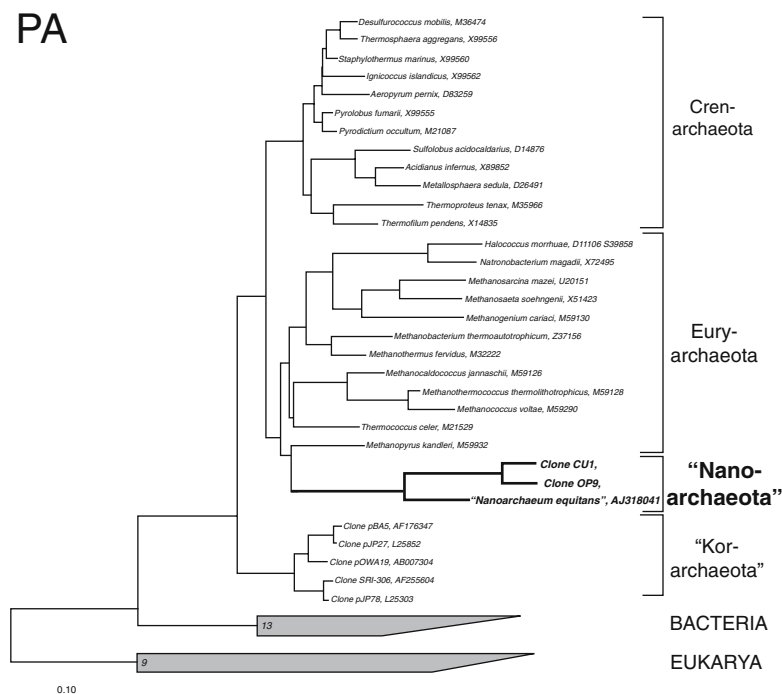

The phylum “*Nanoarchaeota*” was recently described by Huber et al. (2002). At present, the “*Nanoarchaeota*” are comprised of one genus

Fig. 1. Phylogenetic trees based on 16S rRNA sequences. The trees were calculated using NJ, neighbor joining; FM, Fitch Margoliash; PA, maximum parsimony; and FML, maximum likelihood calculation program. Scale bar: 10 estimated exchanges within 100 nucleotides.

NJ

PA

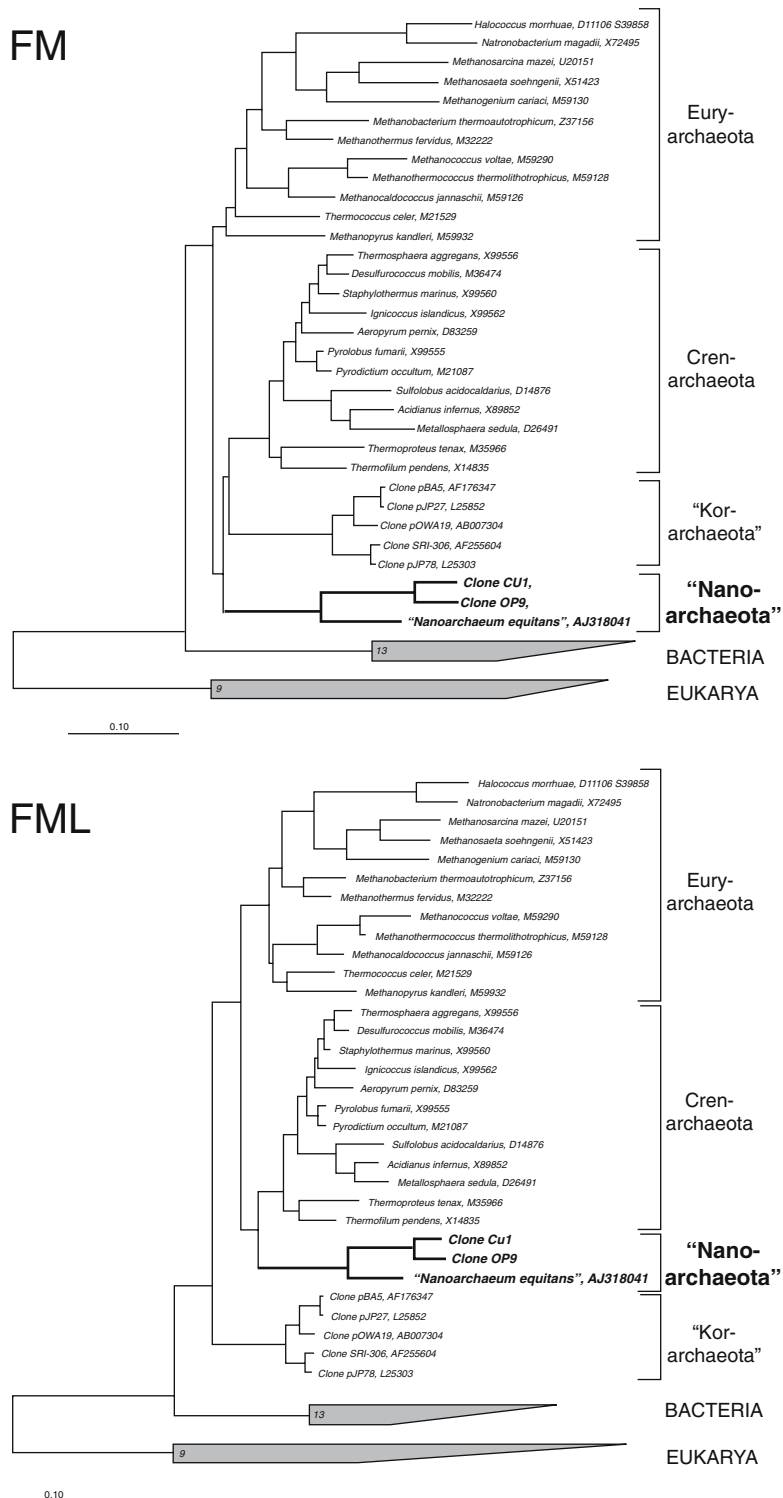

with one species: “*Nanoarchaeum equitans*.” However, this species is not yet formally described, and therefore the name has to be written in quotation marks. Besides this organism, three further “nanoarchaeotal” 16S rDNA sequences from environmental DNAs are known which were obtained from different high temperature biotopes (sequence LPC33 is identical to “*Nanoarchaeum equitans*”; Hohn et al., 2002). So

far, it is unclear whether these new “*Nanoarchaeota*” sequences represent small symbiotic organisms similar to “*Nanoarchaeum equitans*.”

Habitats

“*Nanoarchaeum equitans*” was obtained from a sample of hot rocks taken at the Kolbeinsey

Fig. 1. Continued

Ridge, north of Iceland (Huber et al., 2002). This hydrothermal system is located at the sub-polar Mid-Atlantic Ridge at a depth of around 106 m (Fricke et al., 1989). For the detection of "nanoarchaeotal" 16S rRNA genes, environmental DNAs obtained from a sample collection from high temperature submarine sandy sedi-

ments, venting water, and material from black smokers were investigated. Furthermore, muds, sediments, and spring waters from continental solfataric areas from the same collection were screened. Positive polymerase chain reaction (PCR) amplifications of "nanoarchaeotal" 16S rRNA genes were obtained from a sample of the

East Pacific Rise, designated “LPC33” (black smoker fragment; pH 6.5), and from two continental samples: one found in Obsidian Pool, Yellowstone National Park, United States, designated “OP9” (original temperature 80°C; pH 6.0) and the other in Uzon Caldera, Kamchatka, Russia, designated “CU1” (original temperature 85°C; pH 5.5; Hohn et al., 2002). These results document a broad distribution of members of the “*Nanoarchaeota*” in high temperature biotopes in the deep sea, in shallow marine areas, and in solfataric fields on land. Moreover, the habitats are located on different continents, suggesting a worldwide distribution for “*Nanoarchaeota*.”

Isolation

Enrichment

“*Nanoarchaeum equitans*” has been enriched in 1/2 SME medium, prepared by the use of the anaerobic techniques of Balch and Wolfe (Balch and Wolfe, 1976; see the section Media for Cultivation in this Chapter) by anaerobic incubation at 90°C in the presence of S^0 and H_2/CO_2 (80:20, v/v, 300 kPa) without organic components. Under these conditions a new autotrophic sulfur-reducing species of the archaeal genus *Ignicoccus* could be enriched. In contrast to the *Ignicoccus* species known so far, several *Ignicoccus* cells were covered by very tiny cocci which turned out to represent “*Nanoarchaeum equitans*.” In addition, some “*Nanoarchaeum equitans*” cells existed in the free state.

Isolation Procedures

Anaerobic culture medium is inoculated with 0.5–1 ml (or grams) of the environmental sample. The culture attempts should be checked by

phase-contrast microscopy over a period of up to several weeks for growth. “*Nanoarchaeum equitans*” can be physically isolated either by using “optical tweezers” (Huber et al., 1995; see also the chapter Thermoproteales in this Volume) or by ultrafiltration (pore width: 0.45 μ m). However, all attempts to grow “*Nanoarchaeum equitans*” in pure culture have failed so far. In contrast, the isolation of a combination of a “*Nanoarchaeum equitans*” cell attached to an *Ignicoccus* cell using “optical tweezers” resulted in a defined coculture.

Identification

By electron microscopy, “*Nanoarchaeum equitans*” cells exhibit a rather constant cell diameter of about 400 nm. Their surface is directly attached to the surface of the *Ignicoccus* cells, an outer membrane (Huber et al., 2000; Rachel et al., 2002; Fig. 2a, b and c). No specific attachment structures have been detected so far at the sites of contact, suggesting a loose connection between “*Nanoarchaeum equitans*” cells and *Ignicoccus* cells. In line with this assumption, they can be removed by mild sonification (30 W). “*Nanoarchaeum equitans*” cells do not divide by septa formation and spores are not formed. The organisms stain Gram-negative. Freeze-fracturing, freeze-etching, and ultrathin sections show that the cytoplasm of “*Nanoarchaeum equitans*” cells is surrounded by a cytoplasmic membrane, a 20-nm wide periplasmic space, and an S-layer (regular surface layer) with six-fold symmetry and a lattice constant of 15 nm as the only cell wall component (Huber et al., 2002; R. Rachel, unpublished observation; Figs. 2b and c). The cells can be stained by DNA-specific fluorescence microscopy (DAPI staining). The G+C-content of the genomic DNA is 32 mol%.

Fig. 2. Electron micrographs of cells of “*Nanoarchaeum equitans*” attached to *Ignicoccus* sp. Kin4/I: a) platinum-shadowed; b) freeze-etched; and c) thin section. Bars: 1 μ m (a) and 0.2 μ m (b and c).

Fig. 3. Confocal laser scanning micrograph of “*Nanoarchaeum equitans*” attached to *Ignicoccus* sp. Kin4/I, after hybridization with two oligonucleotide probes specifically designed for the rRNA sequence of each microorganism. “*Nanoarchaeum*”: red (CY3) and *Ignicoccus*: green (rhodamine green). Bar: 5 μ m.

As a major characteristic, “*Nanoarchaeum equitans*” only grows in coculture with *Ignicoccus* strain KIN4/I, indicating a symbiotic mode of life. The final cell density of “*Nanoarchaeum equitans*” in serum bottles is about 3×10^7 cells \cdot ml $^{-1}$, which is in the same range as the maximal cell density of *Ignicoccus* strain KIN4/I. In such a culture, about half of the *Ignicoccus* cells harbor “*Nanoarchaeum equitans*” cells. The number of attached “*Nanoarchaeum equitans*” cells can vary between one to more than ten cells per *Ignicoccus* cell.

The sequence of the 16S rRNA gene of “*Nanoarchaeum equitans*” is so far unique. It harbors many base exchanges, even in so-called “highly conserved regions” usually employed as primer targets for PCR (Huber et al., 2002). Owing to this great divergence, cells of “*Nanoarchaeum equitans*” do not stain by fluorescence *in situ* hybridization (FISH) using 16S rRNA-targeted oligonucleotide probes directed against *Crenarchaeota* and *Euryarchaeota* (e.g., EURY498R and CREN499R; Burggraf et al., 1994). However, after redesigning these oligonucleotide probes on the basis of the “*Nanoarchaeum equitans*” sequence, they exhibit a bright fluorescence (Fig. 3), indicating that “*Nanoarchaeum equitans*” possesses ribosomal RNA harboring the target sequence.

Cultivation

Medium for Cultivation

Culture Medium for “*Nanoarchaeum equitans*”—*Ignicoccus* coculture (1/2 SME-medium, modified)

NaCl	13.85 g
MgSO ₄ \cdot 7H ₂ O	3.50 g
MgCl ₂ \cdot 6H ₂ O	2.75 g

KH ₂ PO ₄	0.5 g
NH ₄ Cl	0.5 g
CaCl ₂ \cdot 2H ₂ O	0.38 g
NaHCO ₃	0.16 g
KCl	0.33 g
NaBr	50 mg
H ₃ BO ₃	15 mg
SrCl ₂	7.5 mg
KI	0.05 mg
Elemental sulfur	10 g
Resazurin	1 mg
Na ₂ S \cdot 9H ₂ O	0.5 g
Distilled water	ad 1 liter

Adjust pH to 6.0, and incubate in a gas phase of H₂/CO₂ (80 : 20) under pressure (300 kPa).

This medium is based on the originally described “SME” medium (Stetter et al., 1983), modified by Pley et al. (1991), and described as “1/2 SME-medium” by Blöchl et al. (1997) and Huber et al. (2000).

Cultivation in Liquid Media

Ignicoccus sp. strain Kin4/I and “*Nanoarchaeum equitans*” are cultivated using the anaerobic technique of Balch and Wolfe (1976).

For small volumes, the organisms are grown in stoppered and pressurized 120-ml serum bottles (Bormioli, Italy) made of “type III” glass. One liter of the corresponding medium is flushed with N₂/CO₂ for 20 min in a 1-liter stoppered glass bottle. Then dissolved oxygen is removed by the addition of 0.5 g of Na₂S \cdot 9H₂O, and the pH is adjusted with H₂SO₄. The medium is dispensed in an anaerobic chamber and finally the culture vessels are pressurized with H₂/CO₂ (80 : 20; 300 kPa) by gas exchange at a gas station. Growth on solidified media is not described for *Ignicoccus* and the “*Nanoarchaeota*.”

Preservation

Ignicoccus sp. strain Kin4/I and “*Nanoarchaeum equitans*” can be stored under anaerobic conditions at 4°C or at room temperatures for several months. The best results for long-term storage are achieved in culture media containing 5% dimethyl sulfoxide and storage in the gas phase over liquid nitrogen (around –140°C). No loss of cell viability is observed after storage of two years.

Physiology

Since growth of “*Nanoarchaeum equitans*” depends on propagating *Ignicoccus* cells (strain KIN4/I), very similar growth parameters are observed for both organisms. Growth of the coculture is only obtained under strictly anaerobic conditions between 70 and 98°C. Optimal growth

occurs at 90°C, pH 6, and a salt concentration of 2% NaCl. The final cell density of “*Nanoarchaeum equitans*” in serum bottles (about 3×10^7 cells \cdot ml⁻¹) can be increased about 10-fold in an enamel protected fermentor (300-liter) by adjusting the gassing rate to 30 liters \cdot min⁻¹ (H₂/CO₂ = 80 : 20). This procedure improves hydrogen supply and efficiently removes H₂S, the main metabolic end product of *Ignicoccus*. Under these conditions, the cell density of *Ignicoccus* remains unchanged. During the late exponential growth phase of such a culture, about 80% of the “*Nanoarchaeum*” cells detach from their host cells and occur freely in suspension.

The host of “*Nanoarchaeum equitans*,” *Ignicoccus* strain KIN4/I, is an obligate chemolithoautotroph using molecular hydrogen as the sole electron donor and elemental sulfur as the electron acceptor (S⁰-H₂ autotrophy). It produces high amounts of H₂S as a metabolic end product. Similar to those described for *Ignicoccus* species, the final cell density and shortest doubling time are not significantly influenced by the addition of organic compounds to the culture medium. In contrast, for “*Nanoarchaeum equitans*” only a few metabolic properties are known so far. Isolated cells do not grow on cell homogenates of *Ignicoccus*; they require an actively growing *Ignicoccus* culture. A wide variety of single and complex organic compounds have been tested but none significantly increased the final cell density of “*Nanoarchaeum equitans*.” “*Nanoarchaeum*” cells locally separated by dialysis bags from *Ignicoccus* cells are unable to propagate. Therefore, a direct cell-cell contact with the host appears to be a prerequisite for growth.

Genetics

The genome of “*Nanoarchaeum equitans*” has been recently sequenced by DIVERSA Corp. (San Diego, CA, United States). It has a length of about 490 kb and is therefore the smallest archaeal genome known so far. Its analysis may provide more insights into the physiology and phylogenetic position of “*Nanoarchaeum equitans*.”

Ecology

“*Nanoarchaeum equitans*” and its host *Ignicoccus* strain KIN4/I have been isolated from a marine hydrothermal system. Other high temperature marine and terrestrial environments harbor further “nanoarchaeotal” sequences. Interestingly, these include continental biotopes with low ionic strength, which are so far unknown biotopes for *Ignicoccus* species. This

gives rise to the questions: is it characteristic for the “*Nanoarchaeota*” to live as symbionts or even as parasites and what organisms can serve as hosts? The existence of “*Nanoarchaeum equitans*” demonstrates that close relationships (symbiosis or parasitism) occur not only between members of different domains, but even within the Archaea.

Acknowledgments. The authors thank Peter Hummel, Bärbel Schwarz and Daniela Näther for help with electron microscopy and Brian Hedlund for critically reading the manuscript. We wish to thank Verena C. Wimmer for providing equipment and advisory help in confocal laser scanning microscopy.

Phylogenetic and Ecological Perspectives on Uncultured Crenarchaeota and Korarchaeota

SCOTT C. DAWSON, EDWARD F. DELONG AND NORMAN R. PACE

Introduction

Molecular phylogenetic analyses divide the domain Archaea into two lineages: Euryarchaeota and Crenarchaeota. Potentially a third main line, Korarchaeota (Woese et al., 1990; Barns et al., 1996), is indicated by only a few environmental sequences and so remains to be further documented. In the late 1970s, at the time of the initial recognition of Archaea as a third domain of life separate from Bacteria or Eucarya, the clade Archaea was thought to consist mostly of “extremeophiles,” organisms inhabiting hostile or unusual settings such as geothermal or hypersaline environments. This perception, which proved to be highly distorted, was founded in the fact that most of the cultivated representatives of Archaea derived from such environments. The diverse physiologies of the cultured examples of Archaea seemed to reflect their settings. Cultured types of Euryarchaeota are physiologically varied, including methanogens, halophiles, and thermophiles. Cultivated members of the Crenarchaeota, on the other hand, have seemed more phenotypically homogeneous. Essentially all cultured Crenarchaeota are sulfur-dependent thermophiles and hyperthermophiles. More recently it has become evident that the cultured organisms represent a minority of crenarchaeal diversity, only one of several phylogenetic groups of Crenarchaeota. The uncultured kinds of organisms have only been encountered through environmental sequence studies. Considering the environmental settings of the uncultured organisms, the majority of types of Crenarchaeota are not thermophiles or “extremeophiles” but rather must be viewed as mesophiles or psychrophiles of uncertain physiology.

Our new understanding of the diversity of Crenarchaeota is due largely to the use of molecular techniques that survey microbial diversity in natural environments without the traditional requirement to pure-culture microorganisms in order to identify them. These molecular techniques mainly use cloning and sequencing rRNA genes from environmental DNA in order to identify the phylogenetic types of organisms, the

“phylotypes,” that comprise the ecosystem analyzed. Since 1992 (DeLong, 1992), environmental crenarchaeal rDNAs have been encountered in such “mundane” temperate settings as the open ocean, terrestrial soils, and freshwater and marine sediments. In addition to the cosmopolitan, non-thermophilic representatives of Crenarchaeota, rRNA sequences have revealed novel thermophilic lineages in geothermal environments around the world, some related specifically to the novel mesophiles. The applications of molecular methods have expanded spectacularly our view of crenarchaeal diversity. The abundance and wide distribution of Crenarchaeota in the environment attest that they play important, still unknown roles in the global ecosystem.

Phylogeny of Crenarchaeota

Our perception of the phylogeny of Crenarchaeota is limited currently to only about 300 small-subunit rRNA sequences, mostly derived from environmental samples. A diagrammatic phylogenetic tree based on these sequences is shown in Figure 1. Although the deeper branchings among the Crenarchaeota are not well resolved, it is nonetheless clear that this primary archaeal clade is comprised of several major sub-clades. There is no formal nomenclature for the uncultured phylogenetic groups thus far established; names of the groups are anecdotal. The phylogeny and taxonomy of specific cultivated representatives of the Crenarchaeota have been summarized (Burggraf et al. 1997a) and are discussed elsewhere in this volume.

Figure 1 is a phylogenetic tree of Crenarchaeota showing positions of uncultivated lineages. This diagrammatic tree is based on multiple bootstrapped analyses using three different phylogenetic methods (maximum likelihood, parsimony, and minimum evolution) to infer the tree topologies. The bootstrap values, determined as percentages of 100 trees inferred by each type of analysis, are given for branches having greater than 50% support (parsimony and minimum

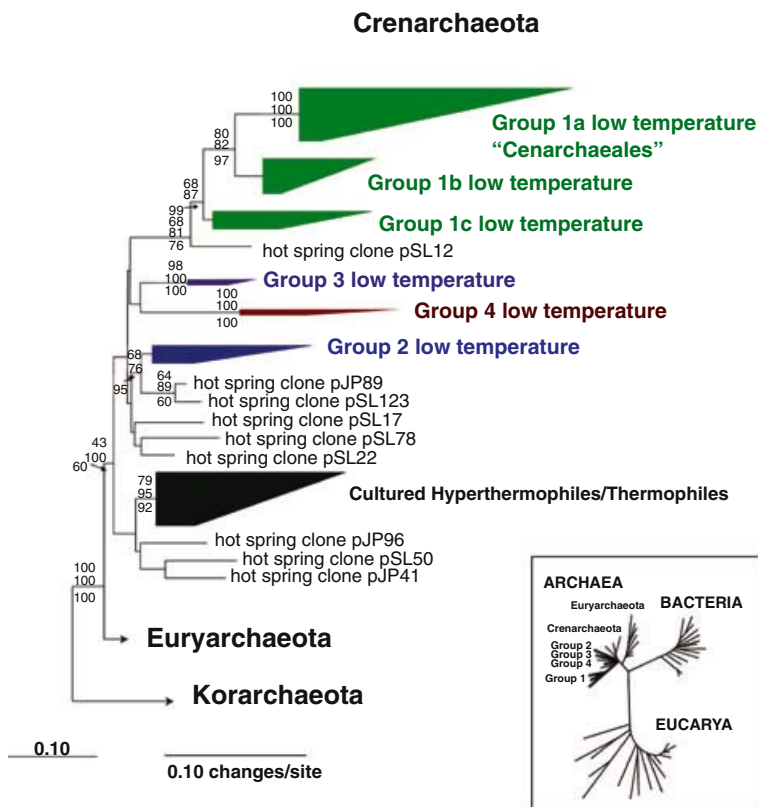

Fig. 1. Phylogenetic analysis of uncultivated Crenarchaeota.

evolution values, above lines respectively, and maximum likelihood values below lines). The scale bar indicates 0.10 changes/site. 56 representative rRNA sequences incorporating 856 unambiguously homologous nucleotide positions were used to create the tree. The size of the wedges is roughly proportional to the number of rRNA sequences in that particular phylogenetic group.

Cultured crenarchaeotes, all thermophiles, are seen to fall into only one of several main relatedness groups, distinct from several other, still uncultured thermophilic and low-temperature clades of equivalent branch-depth in the tree. These Crenarchaeota are only distantly related to the other major clades with no cultivars, about the same in rRNA sequence-divergence as between the bacterial divisions. Thus, by far the majority of known crenarchaeal diversity has no cultured representation. Since only a small number of environmental settings has been examined for representatives of Crenarchaeota, it is unquestionable that our understanding of their evolutionary history and distribution will expand substantially with further study.

rRNA-based phylogenetic trees suggest that the low-temperature lineages generally arose from thermophilic lines. This is based on the fact that low-temperature sequences generally group with thermophilic ones in phylogenetic trees and

the assumption that modern organisms that represent the short branches are most similar in nature to the ancestral kinds of organisms. The relatively long line-segments of low-temperature sequences compared to the thermophilic ones thus would indicate that low-temperature lines were derived from thermophilic ancestry. According to the topology of the emerging crenarchaeal tree (Fig. 1), this happened multiple times.

Korarchaeota

The clade "Korarchaeota" is represented by only a handful of small-subunit rRNA gene sequences; there are no cultivated representatives. The group is significant because of its deeply branching property in phylogenetic trees (Fig. 1). Analyses with small-subunit sequences indicate that the group branches more deeply than even the Crenarchaeota/Euryarchaeota separation and thus would merit the status of a third "kingdom" of Archaea. This result remains to be confirmed, however. The deeply divergent nature of Korarchaeota in phylogenetic analyses is dependent technically on the inclusion of representative eukaryotic rRNA sequences in the analysis. Analyses that include only bacterial and

archaeal sequences associate Korarchaeota with Crenarchaeota (Barns et al., 1996). The status of this group needs to be tested and consolidated by further study of other gene sequences and descriptions of organismal properties.

First encountered in a survey of archaeal rRNA genes in Yellowstone's Obsidian Pool (formerly Jim's Black Pool), sequences representing Korarchaeota have been detected in other Yellowstone hot springs (unpublished). Considering their relatively high abundance where detected, korarchaeotes are likely to be abundant in similar settings globally. Obsidian Pool contains high concentrations of reduced iron, sulfur compounds and probably hydrogen. The biomass there is largely associated with paving stone-like stromatolitic structures. The relatively high abundance of korarchaeotes in that setting, a few percent of rRNA genes in bulk biomass, may indicate that they are engaged in primary production and so are likely to be chemolithotrophic.

Although not yet pure-cultured, the Obsidian Pool organisms detected as rDNA clones JP27 and JP78 have been maintained in consortium and visualized using fluorescent rRNA probes (Burggraf, Heyder et al., 1997b). Both are rod-shaped and occur only attached to surfaces, both common traits of organisms in the environment.

Low-Temperature Crenarchaeota

Low-temperature crenarchaeotes were first discovered during rRNA-based surveys of marine microbiota (DeLong, 1992). Nonthermophilic Crenarchaeota subsequently have been detected in freshwater and marine sediments, terrestrial soils, anaerobic digesters, deep subsurface paleosols, and in association with metazoan species (Table 1). Molecular phylogenetic analyses of the evolutionary relationships among the Crenarchaeota based on small subunit rRNA genes suggest at least four main lineages of non-thermophilic Crenarchaeota (Fig. 1).

Figure 2 gives a summary of rRNA-based molecular phylogenetic surveys of microbial assemblages in which various groups of uncultivated low-temperature representatives of the Crenarchaeota have been identified. Phylogenetic groups of low-temperature Crenarchaeota are shown in Figure 2.

Densities of Group 1 Archaea and Bacteria sampled at the indicated depths were determined by fluorescence hybridization as described (DeLong et al., 1999). The sampling site was approximately 259 km offshore of Moss Landing, CA.

Two of the low-temperature lineages (Groups 1 and 2) are specifically associated phylogeneti-

cally with crenarchaeal sequences identified from Obsidian Pool, a hydrothermal spring in Yellowstone National Park (Barns et al., 1994). The marine crenarchaeal types (Group 1a) first identified by DeLong in the open ocean (DeLong, 1992) are related specifically to rDNA phylotypes that are widely distributed in freshwater aquatic sediments and terrestrial soils (Group 1b). Groups 1a, 1b, and 1c Crenarchaeota are most closely affiliated with the hot spring clone pSL12 and form the most commonly identified clade of non-thermophilic Crenarchaeota in environmental molecular surveys. The order name Cenarchaeales (DeLong and Preston, order nov.) and the family name Cenarchaeaceae (DeLong and Preston, fam. nov.) have been proposed for the clade that contains a metazoan symbiont (below), planktonic and abyssal marine Crenarchaeota (Group 1a) (Preston et al., 1996).

Group 2 low-temperature Crenarchaeota have been encountered in both freshwater and marine anoxic sediments (Hershberger et al., 1996; Schleper et al., 1997a; Chandler et al., 1998) and are most closely related to the hot spring clones pJP89 and pSL123. Apart from Group 1 Crenarchaeota, this clade is the most ecologically widespread. Group 3 and Group 4 Crenarchaeota are represented by only a few rDNA sequences at this time. They are likely sister groups to one another and are not specifically related to a hot spring clone as are the other non-thermophilic lineages (Fig. 1). Sequences representing both Group 3 and Group 4 clades seem to be less abundant types (Table 1). Low bootstrap values associated with positions of Group 3 and Group 4 in phylogenetic trees indicate that their specific branch points are not certain. This could be resolved in the future with the identification of additional members of these groups and their inclusion in tree analyses.

The crenarchaeal evolutionary tree has so far been resolved using small subunit rRNA gene phylogenies. Genomic sequence scans of fosmid clones (below) of Group 1a low-temperature Crenarchaeota, however, have detected other genes that are useful for phylogenetic analyses, including the translational elongation factor EF2 and DNA-dependent RNA polymerase II. Protein phylogenies using either of these genes support the results based on small subunit rRNA phylogenies (Stein et al., 1996; Schleper, 1997b).

Ecological Distribution and Abundance

Estimations of crenarchaeal abundance in the environment can provide clues to the ecology of that environment and provide hints to the phys-

iological roles of these organisms. In the case of uncultured Crenarchaeota it has been necessary so far to rely on rRNA-based molecular approaches to quantify and visualize them. There are, so far, too few studies to generalize regarding representatives of the uncultured high-temperature clades. Limited surveys in Yellowstone thermal springs indicate that crenarchaeal rRNA genes generally constitute a few percent of total rRNA genes in these settings. (Dominant forms are members of the hydrogen-metabolizing bacterial divisions Aquificales and Thermotogales.) The places uncultured crenarchaeotes occur, hot springs rich in hydrogen, Fe(II) and sulfur at many oxidation states, perhaps suggest that their metabolic themes are similar to those of the cultured crenarchaeotes, i.e. hydrogen-sulfur metabolism.

Based on the relative frequencies of different crenarchaeal rDNAs in several globally distributed ecosystems, the Group 1 clade seems to be the most abundant and widespread of all the low-temperature Crenarchaeota (DeLong, 1998). In terms of numbers, the uncultivated low-temperature Crenarchaeota can represent a significant portion of biomass in some environments. For instance, molecular hybridization methods that quantify bulk archaeal or bacterial rRNA in environmental DNA indicate a high abundance of crenarchaeal rRNA in Antarctic waters, ranging from 5–30% of total planktonic rRNA. Further, in surveys of open ocean waters, Group 1a Crenarchaeota appear to reach maximal abundance (20–30% of planktonic rRNA) below 100 m depth (Massana et al., 1997; Murray et al., 1998). An example of the vertical distribu-

Fig. 2. Vertical distribution of Group 1a Crenarchaeota.

tion of Group 1a crenarchaeotes in the ocean is shown in Figure 2 (DeLong et al., 1999). The results indicate that these kinds of organisms constitute a significant component, about 30 percent, of the microbes in the deep sea.

Cloning and rRNA-targeted probing experiments indicate that low temperature Crenarchaeota are more rare in environments that are less oligotrophic than the marine setting, for instance freshwater and soil environments, in which they also are commonly found. In a molecular survey of Archaea in Lake Michigan sediment, members of the Group 1b type of nonthermophilic Crenarchaeota were reported to account for roughly 10% of bulk archaeal rRNA (Macgregor et al., 1997). In addition, non-thermophilic Crenarchaeota in this freshwater environment were found to be of greater abundance in the oxic region, although their range extended into the anoxic zone (Macgregor et al., 1997). A relatively low abundance (roughly 1% of total community rRNA) of Group 1b Crenarchaeota also has recently been reported in agricultural soils (Buckley et al., 1998).

Quantification of bulk archaeal lipids (archaeols) in order to estimate organism abundance is an alternative and complementary approach to rDNA analysis. In contrast to the ester-linked lipids of Bacteria and Eucarya, archaeal lipids (archaeols) are ether-linked. Analysis of such lipids has been used to detect Archaea indirectly in

hypersaline and anoxic environments. The characteristic cyclic and acyclic diphytanyl glycerol tetraether lipids have been used as markers for the presence of Archaea in marine planktonic environments. Cyclic ether-linked lipids are not found in cultured Archaea among the thermophilic Crenarchaeota, but they co-occur with low-temperature Crenarchaeota and so likely occur in those kinds of organisms as well. Based on the abundance of these lipids, crenarchaeotes would seem to be the major biological source of tetraether lipids in the marine planktonic environment. This is additional confirmation of the ecological significance of low-temperature Crenarchaeota (DeLong et al., 1998).

General Biology and Potential Physiologies of Uncultured Crenarchaeota

The physiological properties of uncultured Crenarchaeota are unknown. They are sufficiently different from cultured organisms that such inferences based on known organisms cannot be made reliably. In terms of energy metabolism, cultured representatives of the Archaea as a whole tend toward chemolithoautotrophy, including methanogenesis, and the reaction of sulfur compounds and hydrogen. Aerobic and anaerobic heterotrophic oxidation of carbon compounds are less common. Phototrophic metabolism (probably not resulting in primary production) is limited to the halophiles and, based on culture studies, the distribution of nitrogen fixation is limited. The thermophilic clade of the Crenarchaeota with cultivars is predominantly composed of anaerobic hydrogen and sulfur metabolizers. Uncultured thermophilic crenarchaeotes are abundant in geothermal areas, so they may also be chemolithotrophic. These generalities may hint that low-temperature Crenarchaeota, as well, carry out hydrogen and sulfur metabolism (Hershenberger et al., 1996).

Deduction of the physiology or metabolism of the uncultured Crenarchaeota on the basis of properties of their cultured relatives is complicated by several factors. First, the uncultured clades of Crenarchaeota are only distantly related to any cultured and described organisms. Secondly, physiologic traits are not necessarily always coherent within phylogenetic groups. In some cases, phylogenetic information indeed is useful in inferring physiological properties. For instance, all known methanogens are members of the Archaea, so it is reasonable to presume that methanogenesis is carried out by an uncultivated microorganism that happens to be closely

related to a known methanogen. Such phylogenetic and physiological coherence does not necessarily hold, however. Closely related microbes commonly possess disparate physiologies. *Nitrobacter winogradski* and *Rhodopseudomonas palustris*, for instance, are closely related phylogenetically, but one is a non-phototrophic chemolithotroph and the other is an anaerobic phototroph. These overtly distinct metabolisms, however, belie the fundamental biochemical similarity that is indicated by the close relationships of the organisms. The remote relatedness of the multiple and distinct phylogenetic lineages of thermophilic and low-temperature Crenarchaeota make it possible that each lineage may possess strikingly different physiologies. Perhaps low-temperature crenarchaeal metabolism will prove to be as varied as that of the bacterial divisions.

In the absence of cultures, alternate approaches are required to gain insight into the physiology and metabolism of uncultured crenarchaeotes. Other experimental lines of evidence that do not depend upon cultivation can provide information on the physiology of uncultured Crenarchaeota or any other organism. These include both ecological characterizations and genomic data.

The specific abiotic and biotic properties of the ecological niches of representatives of particular uncultured crenarchaeal lineages offer clues to physiology. For instance, Groups 1a, 1b, and 1c low-temperature Crenarchaeota are common in oxic zones such as agricultural soils and the open ocean and thus likely are aerobic (DeLong, 1994; Hershberger et al., 1996; Bintrim et al., 1997; Jurgens et al., 1997; Macgregor et al., 1997; Buckley et al., 1998). On the other hand, Group 2 low-temperature Crenarchaeota occur in the anaerobic environments of sediments, marshes (Hershberger et al., 1996; Schleper et al., 1997b), and an anaerobic digester (Godon et al., 1997) and so presumably conduct anaerobic metabolism. Group 3 and Group 4 Crenarchaeota also are likely to be anaerobes, based on the occurrence of their rDNA sequences in anoxic marine and freshwater sulfide-rich sediments (Hershberger et al., 1996; Vetriani et al., 1998; Dawson, 2000). Groups 2, 3 and 4 may engage in some form of sulfur metabolism, as similar mechanisms are used by their thermophilic relatives. Both marine and freshwater sediments tend to be rich in sulfur derivatives due to microbial sulfate respiration. Hydrogen metabolism, a common theme among the thermophilic cultivars, is another possibility for some low-temperature crenarchaeotes. Anaerobic environments, particularly, can be rich in molecular hydrogen due to metabolism or to inorganic reactions such as between Fe (II) and water.

Genomic sequences of uncultivated microorganisms offer opportunities to gain insight into their physiological potential in the absence of cultivation studies. Bulk environmental high molecular weight DNA from the environment can be shotgun cloned into vectors capable of carrying large inserts, to create community genomic libraries. Using rRNA sequences as specific tags for a particular microorganism, more genes from particular organisms can be identified by sequencing upstream or downstream from the small subunit rRNA operons. Appropriate vectors can contain up to several percent of a typical archaeal genome, and so, in principle, an entire genome can be assembled from contiguous segments. Two types of non-thermophilic Crenarchaeota have been characterized in this way to some extent: a planktonic (200 m depth) marine crenarchaeote and a sponge-associated organism, *Cenarchaeum symbiosum*.

Several genes in the marine crenarchaeote, including the translational elongation factor EF2, were identified and subsequently used to provide an independent assessment and confirmation of rRNA-based phylogenies. Two other genes, an RNA helicase and GSAT (glutamate-1-semialdehyde aminotransferase), had not previously been found among the Archaea (Stein et al., 1996). GSAT is a component of the pathway for the synthesis of 5-aminolevulinic acid. 5-aminolevulinic acid can be synthesized via two pathways: a C4 pathway (present in animals, fungi, and some bacteria) or a C5 pathway (present in some plants). The crenarchaeal GSAT shares higher similarity to that of the plant GSAT proteins. This is intriguing because the C5 pathway leads to the biosynthesis of chlorophyll.

***Cenarchaeum symbiosum*—A Model for Low-Temperature Crenarchaeota**

An unexpected niche of low-temperature Crenarchaeota is in the specific association of a single crenarchaeal phylotype, *Cenarchaeum symbiosum*, with the sponge *Axinella mexicana* (Preston et al., 1996) (Fig. 3a, b). This archaeal-metazoan association represents the first described symbiosis involving Crenarchaeota. The sponge-crenarchaeote association is specific, with a single crenarchaeal phylotype inhabiting a particular sponge host species. This natural "enrichment" of nonthermophilic Crenarchaeota offers a laboratory source of cells for experimental analysis.

The archaeon *C. symbiosum* inhabits the sponge *Axinella mexicana* (Panel A) and can be cultured in the sponge tissues in appropriate

Fig. 3. *Cenarchaeum symbiosum*, a crenarchaeal sponge symbiont.

aquaria (Panel B). Differential fluorescent staining of *C. symbiosum* reveals that cellular DNA (stained with diamidinophenylindole [DAPI], yellow) is segregated from ribosomes (stained with an rRNA probe, red) (Preston et al., 1996).

Whole cell *in situ* hybridization studies using crenarchaeal-specific oligonucleotide probes have enabled the visualization and quantification of *Cenarchaeum symbiosum* in the tissues of the sponge. This crenarchaeote is a member of the Group 1a marine low-temperature clade and forms small rod-shaped cells of approximately 0.8 μm in length by 0.5 μm in width (Fig. 3c, d). Based on rDNA content, *C. symbiosum* accounts for 65% of microorganisms associated with the sponge (Preston et al., 1996). Actively dividing *C. symbiosum* have been visualized using whole cell hybridization, providing for the first time conclusive evidence of crenarchaeal growth at roughly 10°C (Fig. 3c). Moreover, several genes other than rRNA have been identified in genomic libraries made from purified cell fractions of *C. symbiosum*. One, a DNA polymerase, was studied in some detail. This polymerase

showed the highest sequence-similarity to other crenarchaeal DNA polymerases, many of which are thermostable over 80°C for more than an hour. The sponge-symbiont DNA polymerase was expressed, purified, and studied with regard to some of its properties. The enzyme showed a half-life of ten minutes at 46°C and was inactivated at temperatures greater than 40°C. The thermally sensitive nature of this enzyme is consistent with the non-thermophilic phenotype of the sponge-symbiont, which has been maintained in association with the sponge in aquaria at temperatures of 10°C for several years.

Cenarchaeum symbiosum could prove a useful model for understanding cell division in the Archaea—an area in which little is known and the opportunities are many. Genomic analysis of some instances of Euryarchaeota suggests a unique mechanism of cell division in comparison to that of Bacteria or Eucarya (Bernander, 1998). Additionally, *in situ* hybridization experiments show that ribosomes are excluded from the nuclear region of *C. symbiosum*, a morphology more akin to the nucleus of eucaryotes than

to the dispersed nucleoid of Bacteria (Preston et al., 1996; Fig. 3c). Recent microscopic studies with *Sulfolobus* (Poplowski, 1997) and genomic analysis of methanogens suggest a mechanism for chromosome segregation in the Archaea that may be more comparable to that of the Eucarya than that of the Bacteria. Perhaps the archaeal nuclear zone is a rudimentary version of our own nuclear matrix.

Conclusions

Molecular phylogenetic surveys of representatives of Crenarchaeota in natural environments show that temperature optimum of growth is not a defining characteristic of Crenarchaeota. Indeed, the growth-temperature optima of Crenarchaeota span the full range of life: from -1.5°C in Antarctic waters to over 100°C in sulfuric hot springs. Molecular phylogenies of the Crenarchaeota suggest that non-thermophilic Crenarchaeota derive from relatives adapted to living at higher temperatures. The cosmopolitan distribution of multiple lineages of non-thermophilic Crenarchaeota implies that they play important roles in the terrestrial biosphere. Phylogenetically directed enrichment strategies, combined with ecological and genomic studies, should prove fruitful in determining the physiological and biochemical properties of all these yet-uncultivated microorganisms.

The deeply divergent clade Korarchaeota is so far indicated only by a few rRNA gene sequences, all from high-temperature ecosystems. This phylogenetic group remains to be substantiated by additional sequence or other information.

Introduction to the Taxonomy of Actinobacteria

ERKO STACKEBRANDT AND PETER SCHUMANN

Introduction

During the past 25 years, comparative analysis of sequences of homologous and genetically stable semantides has demonstrated that several classification systems based on morphology and physiology do not reflect the natural relationships among actinomycetes and related organisms. Though today's taxonomists can better recognize the phylogenetic branching pattern of lineages than previous generations of systematists could, this ability obscures the view that previous classification systems also were established in the belief that they reflected conceptual and methodological progress. In this respect, no difference exists in the history of the actinomycetes classification and that of other groups of bacteria. In hindsight, it is their tempo and mode of evolution that make actinomycetes and their relatives difficult to classify outside the context of phylogeny: though the majority of taxa evolved rather late in Earth's history, individual characteristics (traditionally used in early classification) are highly diverse and only rarely reflect phylogenetic relationships.

This chapter highlights the progress in the elucidation of the natural relationships among actinomycetes leading to the inclusion of phylogenetic data into a gene sequence-based higher classification system. Although this taxon, with the introduction of the *Approved Lists of Bacterial Names* (Skerman et al., 1980) and guidelines for the circumscription of species (Wayne et al., 1987), was demonstrated to be a rather coherent entity, significant changes occurred at higher taxonomic ranks. This is true not only for the genus level, for which traditional descriptors play the same key role as in the past, but also more obviously for the ranks between genera and class.

The biology of most actinomycete genera has been covered in the previous edition of *The Prokaryotes* (Balows et al., 1992); some of them have been reclassified or dissected since then. Many additional genera were added in the last decade to the actinobacteria proper, increasing the phylogenetic and epigenetic diversity of the

class, even though the medical, ecological and/or biotechnological importance of these new taxa have not yet been evaluated thoroughly. Table 1 compiles the validly and some invalidly described genera and organizes them into families until January 2000, following the scheme of Stackebrandt et al. (1997). The chapter also covers the taxonomy of new, mainly monogeneric families, as well as several genera for which, as compared to the 2nd edition of *The Prokaryotes* (Balows et al., 1992), no substantial increase in information has been recorded. These taxa may subsequently receive renewed attention that would justify their recognition in future updates. For the time being, only the most important taxonomic features of these taxa will be summarized.

A Note on Early Classification Systems of Actinomycetes

Probably no other group of organisms has been given more taxonomic names than the ray fungi ("Strahlenpilze") or mold bacteria. In some cases, the names were assigned to true fungi and true bacteria. Waksman (1950) lists 31 synonyms of generic names of actinomycetes, among which *Actinomyces*, *Nocardia*, *Micromonospora* and *Streptomyces* are today recognized as valid taxa. Names such as *Asteroides*, *Streptothrix*, *Cladotrix*, *Discomyces*, *Oospora*, *Actinocladothrix* and *Cohnistreptothrix* remain interesting from an historical point of view only.

Between 1877 and the early 1920s, questions about the priority of the name *Actinomyces* were a major issue (Flügge, 1896; Lieske, 1921; Buchanan, 1925). The earliest actinomycete genus described was *Streptothrix* (Cohn, 1875). However, *Streptothrix* was originally assigned to a true fungus (Corda, 1839), and for reasons of priority, the bacterial genus *Streptothrix* was declared invalid.

The terms "actinomycete" and "actinomycetes" originate from the generic name *Actinomyces*, described for the causative agent of actinomycosis, the thread bacterium *A. bovis* (Corda, 1839). As in the case for *Streptothrix*, the validity of the

name “Actinomyces” was challenged initially. Several taxonomists pointed out that the existence of the fungus species *Actinomyces horkelii* (later recognized as an algae; Lieske, 1921) precludes the validity of *Actinomyces bovis* Harz. Nevertheless, for two reasons the name *Actinomyces* for a bacterial genus was accepted: firstly, the name was spelled differently, and secondly, the name “Actinomyces” was apparently only used by the original author Meyen (1827) and “universally regarded as invalid” (Buchanan, 1925). To credit the contribution of Cohn (1872; 1875), the generic name *Streptomyces* combined the names first given to actinomycetes, “Streptothrix” and “Actinomyces” (Waksman and Henrici, 1943).

Classification

The nomenclatural problems also highlight the confusing situation in classification. This period of about 90 years lasted until stringent taxonomic rules were introduced and chemical and molecular methods, helpful in assessment of chemotaxonomic coherency and monophyletic structure of genera, were applied. The early problems, by no means restricted to the actinomycetes, were symptomatic for the decades following the introduction of methods for obtaining pure cultures.

Botanists, by comparing spore formation, budding, and the formation of branches and conidia in bacteria to superficially similar processes in fungi, considered bacteria the lower life forms of Hyphomycetes and Ascomycetes. Consequently, emphasis in taxonomy was placed on morphological criteria (Cohn, 1872; Migula, 1894). Changes in concepts occurred when new properties were determined in bacteria, such as formation of end products, cultural characteristics, color and motility. Over decades, several classification systems were presented simultaneously but the taxonomic units were diffuse, often not described properly and not justified satisfactorily. Guidelines did not exist and it was left to the taxonomist to decide upon which alternative scheme to follow. The eight editions of *Bergey's Manual of Determinative Bacteriology* and the *Index Bergeyana* (Buchanan et al., 1966) are probably the richest historic source compiling changes in concepts in bacterial taxonomy.

Most of the early taxonomic literature states the morphological similarities between actinomycetes (Streptotrichae) and fungi. As summarized by Waksman (1950), the actinomycetes were often considered not only to occupy a position between the true fungi or the Hyphomycetes and the bacteria, but also to represent

the ancestral prototype from which these two groups of organisms evolved. Some workers, like Kruse (1896), stated very clearly that the similarities between the *Streptotrichae* and fungi are superficial only, inasmuch as they are closely related to bacteria, especially to causative agents of diphtheria and tuberculosis. These two groups of bacteria were described as *Corynebacterium* and *Mycobacterium* (Lehmann and Neumann, 1896; Lehmann and Neumann, 1896) and were later, together with the actinomycete genera *Streptothrix* and *Oospora*, united in the family *Mycobacteriaceae* (Chester, 1897). Winslow et al. (1917), stressing the artificial nature of this classification system, included in *Mycobacteriaceae* not only *Actinomyces*, *Mycobacterium* and *Corynebacterium*, but also *Nocardia*, *Leptotrichia* and *Fusiformis*. Shortly thereafter, Buchanan (1917; 1918) proposed the order Actinomycetales, containing the families *Actinomycetaceae* and *Mycobacteriaceae*, a proposal that was generally accepted and published with slight taxonomic revisions in textbooks. Waksman (1950) has given a thorough compilation of classification systems of mycelium-forming actinomycetes from 1904 to 1943.

Because of the massive description of new sporoactinomycete and coryneform species in the 1950s and 1960s, the limitations of the unsatisfying classification schemes became obvious. Küster (1967), referring to the actinomycetes, stated “our conception and system of classification is entirely arbitrary” and Waksman (1967) concluded that it is the lack of an international agreement in establishing criteria dealing with the principles of nomenclature and classification that has been partly, if not largely, responsible for this confusion. The evaluation of chemotaxonomic properties in the 1970s finally convincingly demonstrated the phenotypic heterogeneity of almost all actinomycete genera. At the same time, the establishment of the *Approved Lists of Bacterial Names* (Skerman et al., 1980) marked a turning point in bacterial taxonomy. Only those taxa recognized as being validly described by an international committee of microbiologists were included on this list, and taxa not included lost their status in nomenclature. However, this important achievement did not prevent the presentation of higher taxa that in hindsight were chemotaxonomically and phylogenetically heterogeneous. Major taxonomic rearrangements at the genus and family level were initiated shortly after 1980, first by results of chemotaxonomic analyses alone, and later in concert with results of 16S rRNA sequencing analyses when correcting taxonomic conclusions according to the genomic homogeneity of taxa became feasible (Table 2).

Table 2. Example of classification changes that occurred as the value of taxonomic properties was reassessed.

^aThe year that genera with prior affiliation to the *Micrococcus* (Cohn, 1872) were established. Species of these genera were *Micrococcus* spp. at least once in the history of microbial taxonomy.

The Phylogenetic Aspect

The best known phylogenetic trees of the non-molecular area were first proposed by Kluyver and Van Niel (1936) and, based thereon, by Stanier and Van Niel (1941). According to their schemes, morphologically complex forms (such as sarcinas, spirilla and actinomycetes) evolved independently from morphologically simple spherical forms (Fig. 1). Krassil'nikov (1959), on the other hand, proposed the polyphyletic origin of four individual bacterial lines, one of which was the class Actinomycetes. Gram-positive cocci, through the stage of mycococci, were thought to be degenerated forms of the mycobacteria. Propionic acid bacteria were the bridge between mycobacteria and the lactic acid bacteria. If one excludes the organisms with low DNA G+C content and regards the invalid *Pseudobacterium* to represent the core of *Bifidobacterium*,

Krassil'nikov's proposal for the composition of this class matches closely that of the 16S rDNA-based actinomycetes line of descent (Fig. 2). More recently, the use of morphology to depict evolutionary trends was outlined in a scheme (Prauser, 1975) in which the nocardioform bacteria (Prauser, 1976) were believed to represent the bridging stage between the simple coryneform organisms and the morphologically complex sporeforming actinomycetes. This idea is not supported by the placement of nocardioform organisms (other than sporeforming species) in individual lines of descent.

THE PRESENT STATUS OF ACTINOBACTERIAL CLASSIFICATION Following the recognition that mycelium-forming and non-mycelium-forming Gram-positive organisms with a DNA G+C content of <55 mol% are members of a major line

Fig. 1. Illustration of a possible evolutionary development of bacteria from a single coccus (after Kluyver and Van Niel, 1936; from Clifton, 1950).

of descent (Stackebrandt and Woese, 1979; Stackebrandt and Woese, 1981a; Stackebrandt et al., 1983b), numerous studies were carried out to determine the phylogenetic depth and breadth of this lineage (Embley and Stackebrandt, 1994; Koch et al., 1994; Stackebrandt et al., 1980; Stackebrandt et al., 1981b; Stackebrandt et al., 1983a) and to affiliate organisms to novel taxa in order to match classification with genomic relatedness (Collins et al., 1989; Stackebrandt et al., 1995). Another approach that specifically concentrates on elucidating natural relationships among the actinobacteria is illustrated by the search for possible correlations between the phylogenetic position of taxa and production of pharmacophores by these taxa. Phylogenetic research on more than 110 currently recognized genera of the actinobacteria has resulted in the description of a hierarchic classification system in which a rich taxonomic structure between class and genera was proposed (Stackebrandt et al., 1997). Although the basis for a revised classification scheme is based on the 16S rDNA, this proposal would not have been made without support from the analysis of other molecular markers. Whereas some markers (such as 23S rDNA, ATPase, elongation factor Tu [Schleifer and Ludwig, 1989], and the chaperonine Hsp60 [or GroEL]; Viale et al., 1994) are equivalent to 16S rDNA in covering a broad range of prokaryotic taxa, others such as the Hsp65 (Swanson et al., 1997), the RNase RNA gene (Cho et al.,

Fig. 2. A schematic of the origin (morphological and physiological properties) of actinomycetes and relative taxa (Krassil'nikov, 1959).

1998), the *gyrB* gene (Kasai et al., 2000) and the ribosomal protein AT-L30 sequences (Ochi, 1992; Ochi, 1993) are suitable to cover a narrower range of taxa.

THE HIGHER TAXA The hierarchic system of the actinobacteria (schematically shown in Fig. 3) comprises taxa which have been delineated exclusively on the basis of their phylogenetic coherence and the presence of a pattern of differentiating signature nucleotides (Stackebrandt et al., 1997). This figure includes novel higher taxa which have been described recently or for which novel families are indicated from the phylogenetic position of recently described genera. Phenotypic properties traditionally used to circumscribe higher taxa may coincide with the phylogenetic groupings, but these properties do not influence the decision for the clustering of genera into higher taxa. It is not the presence or absence of a defined nucleotide but the uniqueness of the signature nucleotide pattern that circumscribes a higher taxon (Table 3). The rationale for selecting phenetic (instead of phenotypic) characters of the genome to circumscribe higher taxa lies in the availability of genetically stable markers. However, as in other classification systems, the addition of novel taxa may lead to conflicts with the data basis of the present system: some nucleotides may fit into the set of designated properties, whereas others may differ. Another problem is the shift of the phylo-

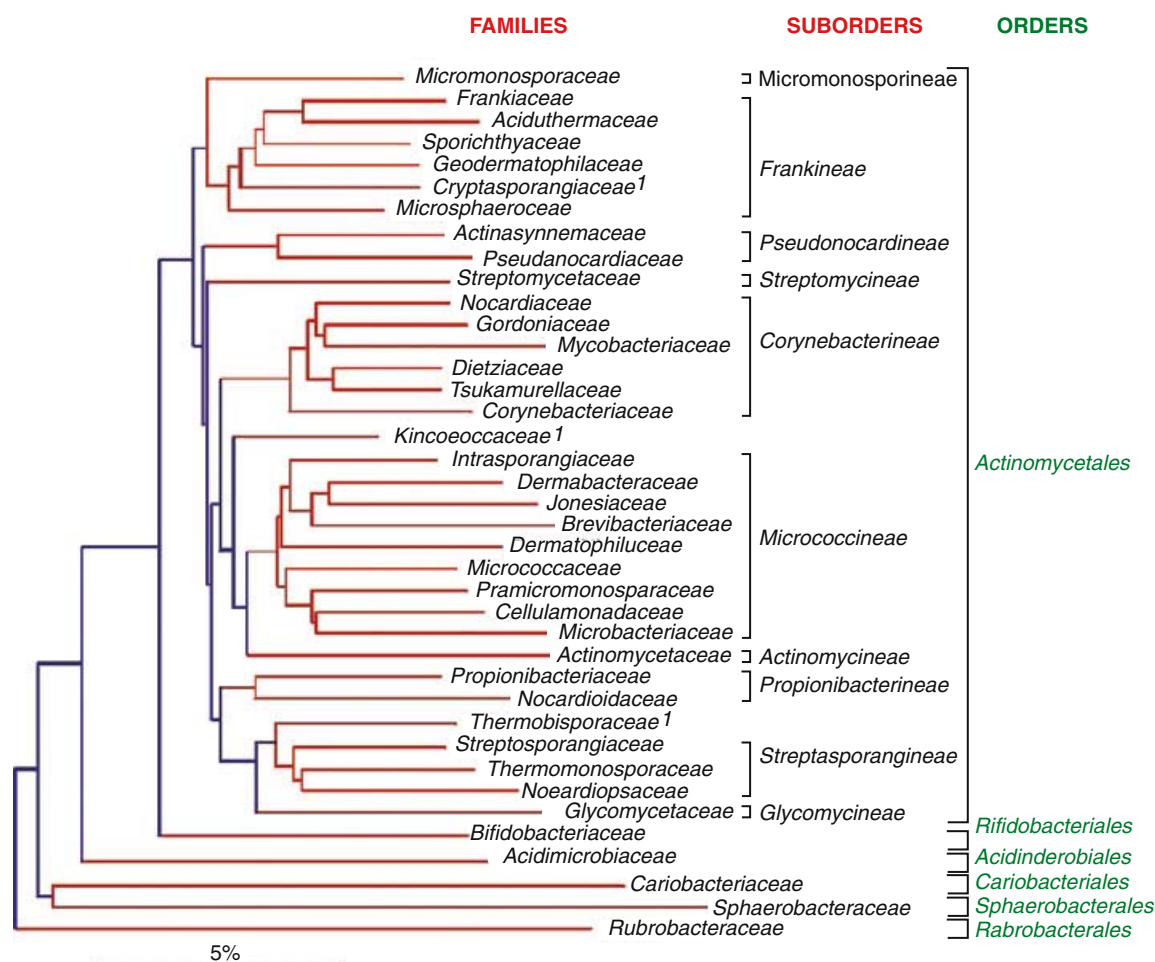

Fig. 3. Intra-class relatedness of Actinobacteria, based upon 16S rDNA/rRNA sequence comparison. The scale bar represents 5 nucleotide substitutions per 100 nucleotides. (Modified from Stackebrandt et al., 1997, with permission.)

genetic place of a taxon or the split of a hitherto homogeneous taxon by the introduction of a genus (Ludwig, 1999; Stackebrandt, 1999), which requires a redefinition of the circumscribing properties. The branching points of suprageneric lineages within the class Actinobacteria are not supported by high statistical significance and shifts in the order of lineages may occur, however, without changing the species composition of genera. For example, the introduction of several novel species into established genera and of novel genera into the suborder *Micrococcineae* has changed the branching order of some lineages, which resulted in the removal of the genera *Rarobacter* and *Sanguibacter* from the families *Cellulomonadaceae* and *Intrasporangiaceae*, respectively, and has led to the dissection of *Dermatophilaceae* (Stackebrandt and Schumann, 2000). Taxonomists are aware that changes are an intrinsic part of any classification

strategy, but newcomers to the field may be confused by the constant but unavoidable corrections of the phylogeny-based system to keep classification in step with insights into natural relationships.

The system as outlined by Stackebrandt et al. (1997) for the ranks between the ranks of genus and class is based on the most thoroughly studied gene(s) available at the time of publication. It cannot be excluded that emphasis will shift to other or to additional homologous genes that may indicate more relatedness or offer more power to discriminate than the 16S rDNA does. One example (the *gyraseB* gene sequence) may offer valuable nucleotide information for spreading distances at the intragenomic level.

SPECIES AND GENERA Though information on the describing properties of ranks above the genera has little importance in the identification

^b*Dermatophilus chelonae*.

Adapted from Stackebrandt et al., 1997.

process, the availability of a rich spectrum of information describing species is indeed crucial. The polyphasic approach to classification provides the microbiologists with sufficient data to decide unambiguously whether a new isolate represents a new or an established species of a new or established genus (Stackebrandt, 1988; Stackebrandt, 1992c). At the generic level, the high correlation between phylogenetic position of the 16S rDNA and chemotaxonomic properties is striking. The finding of a unique pattern of chemotaxonomic characteristics in a novel isolate will in almost all cases be confirmed by the emergence of a novel 16S rDNA lineage falling outside the radiation of a known genus, and vice versa. In a few instances only, despite the presence of differentiating chemical properties, sequence data have revealed that these lineages fall within the realm of a genus; examples are the presence of ornithine and lysine in the peptidoglycan of some bifidobacterial species, of meso-diaminopimelic acid (*meso*-A₂pm) and L, L-diaminopimelic acid (LL-A₂pm) in members of *Streptomyces*, *Kitasotospira* and *Kineosporangium*, and the markedly different peptidoglycan compositions found in closely related species of *Micrococcus luteus* and *M. lylae*. As explained for the importance of working with signature nucleotides of 16S rDNA in the definition of higher taxa, it is not the presence or absence of an individual chemotaxonomic marker but the profile of different markers that is valuable in recognizing and classifying genera. Tables 4 to 11 provide some examples from the suborder *Micrococcineae* which demonstrate the superiority of chemical data in the delineation of genera within Actinobacteria.

It has been argued that care is needed to distinguish morphologically similar organisms, such as members of *Dermacoccus*, *Kocuria*, *Micrococcus*, *Nesterenkonia* and *Stomatococcus*, from each other, from phylogenetically related taxa (Fig. 4) and from other Gram-positive and catalase-positive cocci (Goodfellow, 1998). Other examples are likewise true for the delineation of mycelium-producing organisms and rod-shaped forms. This word of warning is justified if addressed to taxonomists of the pre-chemotaxonomic and pre-molecular era. Classification and subsequently identification have developed into a demanding biological discipline in which taxonomic judgment has lost much of its subjective basis. The affiliation of an organism to its nearest phylogenetic neighbor by determination and comparative analysis of appropriate nucleotide sequences has become easier and faster than determination of a wide range of chemotaxonomic properties, fulfilling the same purpose.

Fig. 4. Phylogenetic relatedness among genera of the suborder *Micrococcineae*, order *Actinomycetales*, class *Actinobacteria*, based upon 16S rDNA/rRNA sequence comparison. Numbers within the dendrogram indicate the percentages of occurrence of the branching order in 500 bootstrapped trees (only values of 70 and above are shown). Sequences of species of other actinobacterial families served as a root. The scale bar represents 5 nucleotide substitutions per 100 nucleotides.

CLASSIFICATION OF TAXA NOT COVERED IN DETAIL The following subchapters are short summaries of taxonomic information on either genera that have been compiled in the 2nd edition of *The Prokaryotes* (Balows et al., 1992) but are not included in the present edition or genera that have been described since 1991. The current information about the latter taxa is often not sufficient to be covered in individual chapters. Once these organisms receive the attention they deserve on the basis of their unique phylogenetic position, this situation may change. Some of the genera dealt with in *The Prokaryotes*, 2nd edition, are covered only briefly here because not much information other than the phyloge-

netic position has changed during the past decade. Still representing the state-of-the-art knowledge on these organisms, these chapters on *Micrococcus* (Kocur et al., 1992), *Renibacterium* (Embley, 1992), *Stomatococcus* (Stackebrandt, 1992c), *Dermatophilaceae* (Stackebrandt, 1992a), and *Arthrobacter* (Jones and Keddie, 1992) include thorough information on isolation, preservation and identification of strains and species and provide descriptions of habitats, biochemical and physiological properties and the biotechnological potential of these strains and species. Classification into risk groups, i.e., according to their pathogenic potential, follows the guidelines of the European Commission 90/679/EEG from November 26th, 1990.

The Deeply Branching Actinobacterial Families

Rubrobacteraceae The monogeneric family *Rubrobacteraceae* has been described as the most deeply branching lineage of the Actinobacteria proper. The genus *Rubrobacter* contains two species of Gram-positive, thermophilic bacteria (48–60°C), namely *R. radiotolerans* (the former *Arthrobacter radiotolerans*; Yoshinaka et al., 1973) and *R. xylanophilus* (Carreto et al., 1996). The type strains are chemotaxonomically characterized by peptidoglycan of type A3 α (L-Lys-L-Ala), major respiratory quinone—menaquinone MK-8, fatty acids—12-methylhexadecanoic and 14-methyloctadecanoic acids, and several phospholipids. *Rubrobacter radiotolerans* has been isolated from a hot spring in Japan after gamma irradiation of water samples, and it has an inactivation dose of 10,000 Gy, which is 2,000 times greater than that of human cells (Saito et al., 1994). Neither the natural habitat of *R. xylanophilus* (isolated from a thermally polluted industrial runoff; Laura et al., 1996) nor the inactivation dose of gamma irradiation of its strains is known.

Several strains that phylogenetically cluster with *Rubrobacter* strains were isolated from soil from an Atacama Desert site in Chile. Analysis of a 16S rDNA clone library, generated from DNA extracted from the same environment, also revealed *Rubrobacter*-type sequences that differed from those of described species and the isolates (F. A. Rainey, personal communication). This highly arid soil is constantly bombarded with high doses of ultraviolet (UV) light, and soil thus may constitute one natural niche of these organisms. The DNAs recovered from a microbial mat associated with the Great Artesian Basin, Australia (Byers et al., 1998), from a subtropical Australian forested soil (Liesack and Stackebrandt, 1992), from a peat bog in North-

ern Germany (Rheims et al., 1996), and from various other environments have provided 16S rDNA clone sequences that appear to remotely link these uncultured organisms to the *Rubrobacter* lineage. However, their branching points are not supported by high statistical significance (Rheims et al., 1999). The degree of phenotypic similarity between *Rubrobacter* strains and the organisms from which DNA has been analyzed must await their cultivation.

SPHAEROBACTERACEAE This family contains the monospecific genus *Sphaerobacter* with the type species *S. thermophilus*. The organism is aerobic, Gram-positive, pleomorphic and nonsporeforming and constitutes part of the dominating flora of aerobe-thermophilically treated sewage sludge (Demharter et al., 1989). Like rubrobacteria, *S. thermophilus* is thermophilic (optimum 55°C), the principal menaquinone is MK-8 and the G+C content of DNA 65 mol%; L-ornithine is the diamino acid at position 3 of the peptide subunit and the interpeptide bridge consists of β -alanine (A3 β -type). Information on polar lipids and fatty acids is absent. Reports (other than the original description) on the presence and distribution, the ecological significance, and additional genomic or phenetic properties also are unavailable.

ACIDIMICROBIACEAE This family embraces the monospecific genus *Acidimicrobium*. Rod-shaped, *A. ferrooxidans* is Gram-positive, moderately thermophilic (45–50°C), ferrous-iron-oxidizing and acidophilic (optimum around pH 2.0), with a DNA G+C content of 69 mol% (Clark and Norris, 1996). Autotrophic growth occurs on ferrous iron. The strains recognized so far were isolated from a test copper leaching system and a hot spring in the United States (strain TH3; Brierley, 1978) and a pyrite enrichment from an Icelandic geothermal site (type strain DSM 10331). The two strains differ in their morphology in that strain TH3 grows in filaments. Growing mixotrophically, strains of *Acidimicrobium* and *Sulfobacillus* oxidize ferrous iron under air more extensively than either strain does in pure culture (Clark and Norris, 1996).

Acidimicrobium strains are the only actinobacteria reported to thrive in warm, acidic, iron-, sulfur- or mineral-sulfide-rich environments, thus expanding the physiological capabilities of members of this class to lithotrophy.

Acidimicrobium thermooxidans is remotely related to “*Microthrix parvicella*” (87% 16S rDNA sequence similarity; Blackall et al., 1994). “*M. parvicella*” is a Gram-positive straight filamentous bacterium (300 to 500 μ m long) that is the major causative agent of foaming and

bulking in activated-sludge sewage-treatment plants (Christensson et al., 1998). Its poor growth on artificial media did not allow physiological testing, and the organisms could not be stored successfully. Similar to strains of *Acidimicrobium*, "M. parvicellum" requires reduced forms of sulfur to grow on artificial media (Blackall et al., 1994).

One of the most surprising results of molecular environmental studies was the emergence of several novel 16S rDNA sequence clusters with probable world-wide distribution in different terrestrial environments. Phylogenetic analyses revealed remote relationships of hitherto uncultured organisms to the family *Acidimicrobiaceae*, where they formed several deeply rooting lineages (Rheims et al., 1999). Members of these clusters originate in subtropical forest soil from Mount Coo-tha, Australia (Stackebrandt et al., 1993), peat bogs of Northern Germany (Rheims et al., 1996), grass soil of The Netherlands (Felske et al., 1997), paddy fields of Japan (Ueda et al., 1995), geothermally heated soil of New Zealand (Rainey et al., 1993), and even in the marine environments (Fuhrman et al., 1993).

CORIOBACTERACEAE Two genera have originally been included into this family, *Coriobacterium* and *Atopobium* (Rainey and Stackebrandt, 1994), whereas two new genera, *Slackia* and *Eggerthella*, have recently been added to the family. The anaerobic species *Coriobacterium glomerans* has been isolated from the intestine of the red soldier bug *Pyrrhocoris apterus* (Haas and König, 1988), and *Atopobium* species were described for some misclassified *Lactococcus* and *Streptococcus* species (Collins and Wallbanks, 1992) isolated from human gingival crevices or from blood, wounds and abscesses (Olsen et al., 1991). Species of these genera share some morphological and chemotaxonomic properties. Cells of both taxa are Gram-positive, nonsporeforming rods to cocci with cells containing central swellings or large spherical intercellular involution forms, respectively. Peptidoglycan is of the A6-type, either the lysine- aspartic acid (Lys-Asp) crosslinkage (*A. parvulum* and *C. glomerans*) or the lysine-serine-glutamic acid (Lys-Ser-Glu) crosslinkage (*A. minutum*). End products of glucose fermentation include lactic and acetic acids. Differences between members of the two genera are found in the composition of additional end products of glucose fermentation, but above all in the base composition of DNA, which is 76 mol% G+C for *C. glomerans* and 35–46 mol% G+C for *Atopobium* species. The latter values are low considering that the vast majority of actinobacteria have mol% G+C values above 55%.

The novel genera were added to the family following 16S rDNA analyses. *Eubacterium exiguum* and *Peptostreptococcus heliothrinreducens* were reclassified as members of *Slackia*. "Denitrobacterium detoxificans," a ruminal bacterium that respire on nitrocompounds, branches distantly to members of this genus (16S rDNA sequence cited as "unpublished" in *European Molecular Biology Laboratory* [EMBL]; Anderson et al., 1997). *Eubacterium lentum* was reclassified as *Eggerthella lenta* (Wade et al., 1999), whereas *Eubacterium fossor* branches within the radiation of the genus *Atopobium*, representing a new species of this genus.

GLYCOMYCINEAE This family has been described for the genus *Glycomyces* that forms a deeply branching individual 16S rDNA line of descent within the order Actinomycetales. The type strains of the three species of the genus are aerobic, produce nonfragmenting vegetative hyphae and form chains of conidia on aerial sporophores (Labeda et al., 1985; Evtushenko et al., 1991). Chemotaxonomically, the amycolate strains are defined by peptidoglycan containing *meso*-A₂pm and glycine, xylose and arabinose as whole cell sugars, phosphatidylinositol, diphosphatidylglycerol and numerous acylated phosphatidylinositol mannosides, menaquinones of type MK-9(H₆), MK-10(H₂), MK-10(H₆), and MK-11(H₆), and a DNA G+C content ranging between 71 and 73 mol%. (Note that MK-9, -10 and -11 are unsaturated menaquinones with nine, ten and eleven isoprene units, respectively; MK-X (H₂) and (H₆) are partially saturated menaquinones and one and three of X isoprene units are hydrogenated, respectively.) Fatty acids determined for the type strain of *G. tenuis* (Evtushenko et al., 1991) are mainly branched *iso*- and *anteiso* acids. The validity of the genus was subsequently confirmed by 16S rDNA analysis which remotely related this genus to the families *Streptosporangiaceae*, *Nocardiopsaceae*, *Thermomonosporaceae* and to the genus *Thermobispora*. The species *G. harbinensis* produces the antibiotic azaserine.

KINEOCOCCACEAE Based upon 16S rDNA sequence analysis, members of the two morphologically very different genera (Table 4) are distantly related (92% similarity) and they were shown to form a separate line of descent within the order Actinomycetales (Miyadoh, 1977; Kudo et al., 1998). The statistical significance of the branching point of this lineage, however, although reported to be as high as 98% by Kudo et al. (1998), is not stable and changes with the selection of reference organisms. If, for example, emphasis is placed on members of the suborder *Micrococcineae* or *Frankineae*, the *Kineococcus*-

Table 4. Morphological and chemotaxonomic characteristics of the genera *Kineococcus* and *Kineosporia*.

Genus	Morphology	Diamino acid	Glycine present	Major menaquinone ^a	Polar lipids	Predominant cellular fatty acid(s)	Whole cell sugars	Mol% G+C
<i>Kineococcus</i>	Motile spherical cells in clusters	meso-A ₂ pm	–	MK-9(H ₂)	PG, DPG, PL	ai-C _{15:0}	Ara, Gal	74
<i>Kineosporia</i>	Vegetative hyphae, “spore domes,” motile spores	meso-A ₂ pm and/or LL-A ₂ pm	+	MK-9(H ₄)	PC	C _{16:0} , C _{18:1} , 10-Me-C _{18:0}	Gal, Glc, Man, Rib, Rha, 3-O-Me-Rha	69–71

Abbreviations: A₂pm, diaminopimelic acid; PG, phosphatidylglycerol; ai-C_{15:0}, 12-methyltetradecanoic acid; DPG, diphosphatidylglycerol; PL, unidentified phospholipid; Ara, arabinose; Gal, galactose; LL-A₂pm, L,L-diaminopimelic acid; PC, phosphatidylcholine; C_{16:0}, hexadecanoic acid; C_{18:1}, octadecenoic acid; 10-Me-C_{18:0}, 10-methyloctadecanoic acid (tuberculoostearic acid); Glc, glucose; Man, mannose; Rha, rhamnose; and Rib, ribose; 3-O-Me-Rha, 3-O-methylrhamnose.

^aMK-9(H₂) and MK-9(H₄) are partially saturated menaquinones with two and four of nine isoprene units hydrogenated, respectively.

Data are from Yokota et al., 1993; Kudo et al., 1988.

Kineosporia lineage is not branching outside but inside the radiation of the respective suborders. In fact, binary similarity values between individual species of *Kineococcus* and *Kineosporia* and members of these suborders are as high as those found for some species of *Kineococcus* and *Kineosporia*. Also, almost all of the 16S rDNA signature nucleotides defined for taxa of *Micrococcineae* are present in the sequences of the latter genera. Hence, the taxonomic affiliation of the two genera is not yet settled and sequences of more representatives of these genera are needed to obtain a more stable view of their relatedness. Only then can the question be answered of whether the two genera are monophyletic and members of the same family. It is noteworthy that the spores (2 µm in diameter) of *Kineosporia* (Pagani and Parenti, 1978) and the cells (1–1.5 µm in diameter) of *Kineococcus* are motile due to a polar tuft of flagella. This finding could lead to the suggestion that *Kineococcus* strains may represent the locked stage of the *Kineosporia* spore stage.

Kineosporia strains were isolated from plant samples found in Japan, and *Kineococcus aurantiacus* was isolated from a soil sample in India. Information other than taxonomic descriptions is not available for these organisms (Table 4).

MEMBERS OF THE SUBORDER MICROCOCCINEAE This suborder contains a rich family structure embracing organisms with very diverse morphology and chemotaxonomic characteristics; one example is *Microbacteriaceae*, differing markedly from the other organisms in the peculiar crosslinkage of peptidoglycan. The addition of novel organisms has made rearrangement of the

taxonomic structure to some extent necessary (Stackebrandt and Schumann, 2000) to maintain the correlation of taxonomic ranks with their phylogenetic position (Stackebrandt et al., 1997).

BOGORIELLACEAE The genus *Bogoriella* with the type species *Bogoriella caseilytica* was described to accommodate a single alkaliphilic strain with unusual taxonomic properties (Groth et al., 1997). The strain was isolated from soda soil (pH 10) near Lake Bogoria in the Kenyan-Tanzanian Rift Valley, Africa. Cells of the organism are more or less aggregated irregular rods or cocci with spiky structures distributed over the surface of each cell. In addition to the morphological features unique among coryneform bacteria, the organism displays uncommon chemotaxonomic characteristics. The peptidoglycan type A4α based on L-lysine (Schleifer and Kandler, 1972) in combination with the occurrence of MK-8(H₄) as predominating menaquinone has not been reported earlier and was only reported recently in the single strain of *Demetria terragena* (Groth et al., 1997a). *Bogoriella caseilytica* differs from *D. terragena*, e.g., in its peptidoglycan interpeptide bridge consisting of two residues of L-alanine and one of L-glutamic acid (Table 5), which represents a novel variation of the peptidoglycan type A4α. The 16S rDNA sequence comparison revealed that *B. caseilytica* represents a distinct lineage within the order Actinomycetales and exhibits less than 94% similarity to the next phylogenetic neighbors (Groth et al., 1997). The family *Bogoriellaceae* has recently been proposed to accommodate the monogeneric taxon *Bogoriella* (Stackebrandt and Schumann, 2000).

Table 5. Chemotaxonomic characteristics of the genus *Bogoriella* representing the family *Bogoriellaceae*.

Genus	Diamino acid	Interpeptide bridge	Major menaquinone	Polar lipids	Predominant cellular fatty acids	Mol% G+C
<i>Bogoriella</i>	L-Lys	L-Ala-L-Ala-L-Glu	MK-8(H ₄)	PI, PG, DPG, PL	ai-C _{15:0} , i-C _{15:1} , i-C _{16:0}	70

Abbreviations: Lys, lysine; Glu, glutamic acid; MK-8(H₄), partially saturated menaquinone with two of eight isoprene units hydrogenated; PI, phosphatidylinositol; Ala, alanine; i-C_{15:1}, 13-methyltetradecenoic acid; and C_{16:0}, hexadecanoic acid. Refer to the footnotes in Table 4 for definitions of all other abbreviations.

Data are from Groth et al., 1997.

Table 6. Chemotaxonomic characteristics of genera of the family *Dermabacteraceae*.

Genus	Diamino acid ^b	Interpeptide bridge ^b	Major menaquinones ^c	Polar lipids ^d	Predominant cellular fatty acids ^e	Mol% G+C	Acyl type ^b
<i>Dermabacter</i>	meso-A ₂ pm	None	MK-9, MK-8, MK-7	PG, DPG, PL, GL	ai-C _{17:0} , ai-C _{15:0} , i-C _{16:0}	62	n.d.
<i>Brachybacterium</i>	meso-A ₂ pm	D-Glu-D-Glu ^a or D-Asp-D-Glu ^a	MK-7, MK-8	PG, DPG, GL	ai-C _{15:0} , ai-C _{17:0}	68–72	Glycolyl

Abbreviations: MK-7, -8, -9, unsaturated menaquinones with seven, eight and nine isoprene units, respectively; ai-C_{17:0}, 14-methylhexadecanoic acid; n.d., not determined; GL, unidentified glycolipid; and Asp, aspartic acid. Refer to the footnotes in Tables 4 and 5 for definitions of all other abbreviations.

^aGlycine amide is bound to glutamic acid at position 2 of the peptide subunit.

Data are from Bogdanovsky et al., 1971; Collins et al., 1988; Jones and Collins, 1988; Gvozdyak et al., 1992; Takeuchi et al., 1995; Schubert et al., 1996.

DERMABACTERACEAE The family *Dermabacteraceae* (Stackebrandt et al., 1997) was established on the basis of 16S rDNA sequence data and circumscribed by a set of specific signature nucleotides. It contains the genera *Dermabacter* (Jones and Collins, 1988) and *Brachybacterium* (Collins et al., 1988). The genus *Dermabacter* (Jones and Collins, 1988) is monospecific and contains the type species *Dermabacter hominis*. Strains of this human cutaneous coryneform bacterium are facultatively anaerobic and characterized by a directly crosslinked peptidoglycan based on meso-A₂pm (variation A1γ; Schleifer and Kandler, 1972). Mycolic acids are absent. *D. hominis* can be distinguished from morphologically similar species of the genus *Brevibacterium*, exhibiting the same combination of the latter two characteristics, by its totally unsaturated menaquinones (Table 6), physiological properties and its separate phylogenetic position as revealed by 16S rDNA sequence analysis (Cai and Collins, 1994). A normal inhabitant of healthy human skin, *D. hominis* is considered non-pathogenic.

Brachybacterium faecium was described to accommodate three strains isolated from poultry deep litter (Collins et al., 1988). Two of these strains were later reclassified as members of two new *Brachybacterium* species, strain NCIB 9859 (together with nine strains of "Micrococcus conglomeratus") as members of *B. conglomeratum* and strain NCIB 9861 as the type strain of *B.*

paraconglomeratum (Takeuchi et al., 1995). Takeuchi et al. (1995) also proposed the strain isolated from corn steep liquor, *B. rhamnosum*, so-called because it contains large amounts of rhamnose in its cell wall. *Brachybacterium nesterenkovii* strains were isolated from dairy products (Gvozdyak et al., 1992), whereas *B. alimentarium* and *B. tyrofermentans* were isolated from the surface of French cheeses (Schubert et al., 1996). All representatives of the genus *Brachybacterium* exhibit a rod-coccus growth cycle and are characterized by the peptidoglycan variation A4γ based on meso-A₂pm (Schleifer and Kandler, 1972), muramic acid in the glycolylated form, absence of mycolic acids, MK-7 as principal menaquinone, and predominance of anteiso-branched cellular fatty acids (Table 6). Whereas the peptidoglycan of the A4γ variation of *B. alimentarium* and *B. tyrofermentans* is cross-linked via an interpeptide bridge consisting of D-aspartic acid and D-glutamic acid, the interpeptide bridges of all other *Brachybacterium* species contain two D-glutamic acid residues. Except for *B. nesterenkovii*, all *Brachybacterium* species have glycine amide bound to the α-carboxyl group of D-glutamic acid at position 2 of the peptide subunit. Members of the genera are considered nonpathogenic.

DERMATOPHILACEAE AND DERMACOCACEAE The family *Dermatophilaceae* (Austwick, 1958) was initially described to include the genera

Table 7. Chemotaxonomic characteristics of genera of the families *Dermatophilaceae* and *Dermacoccaceae*.

Genus	Diamino acid	Interpeptide bridge	Major menaquinone(s)	Polar lipids	Predominant cellular fatty acids	Mol% G+C
<i>Dermatophilus</i>	meso-A ₂ pm	None	MK-8(H ₄)	PG, DPG, PI	C _{16:0} , C _{15:0} , C _{14:0}	57–59
<i>Dermacoccus</i>	L-Lys	L-Ser _{1,2} -D-Glu or L-Ser _{1,2} -L-Ala-D-Glu	MK-8(H ₂)	PI, PG, DPG	i-C _{17:0} , ai-C _{17:0} , i-C _{17:1}	66–71
<i>Kytococcus</i>	L-Lys	D-Glu ₂	MK-8, MK-9, MK-10	PI, PG, DPG	ai-C _{17:0} , C _{17:0} , i-C _{17:1}	68–69
<i>Demetria</i>	L-Lys	L-Ser-D-Asp	MK-8(H ₄)	PI, PE, PG, DPG, PL	C _{18:1} , C _{18:0} , C _{17:0} , ai-C _{17:0}	66

Abbreviations: C_{15:0}, pentadecanoic acid; C_{14:0}, tetradecanoic acid; MK-8(H₂) and MK-8(H₄), partially saturated menaquinones with one and two of eight isoprene units hydrogenated, respectively; i-C_{17:0}, 15-methylhexadecanoic acid; i-C_{17:1}, 15-methylhexadecenoic acid; MK-8, -9, and -10, unsaturated menaquinones with eight, nine and ten isoprene units, respectively; Ser, serine; PE, phosphatidylethanolamine; and C_{18:0}, octadecanoic acid. Refer to the footnotes in Tables 4, 5 and 6 for definitions of all other abbreviations.

Data are from references Gordon, 1989; Groth et al., 1997a; Kocur, 1986; Stackebrandt et al., 1983; Kroppenstedt (Ph.D. thesis), 1977; and Stackebrandt et al., 1995.

Dermatophilus and *Geodermatophilus* which have in common the same type of cell division, i.e., in both transverse and longitudinal planes. Because members of both genera have markedly different growth characteristics, chemotaxonomic properties and 16S rRNA cataloguing data (Stackebrandt et al., 1983c), it was proposed that the family *Dermatophilaceae* be restricted to one genus *Dermatophilus* (Stackebrandt, et al., 1992). Based on 16S rDNA sequence data and presence of specific signature nucleotides, the family *Dermatophilaceae* was emended (Stackebrandt et al., 1997) to contain the type genus *Dermatophilus* (Van Saceghem, 1915; Gordon, 1964) as well as the genera *Dermacoccus* (Stackebrandt et al., 1995) and *Kytococcus* (Stackebrandt et al., 1995).

With the addition of novel species into *Micrococcineae*, the incoherence of the family *Dermatophilaceae* became obvious in that the type genus of *Dermatophilus* clustered separately from those of the remaining two genera (Fig. 4). Consequently, the family has been split into *Dermatophilaceae* and *Dermacoccaceae*, with the latter family to embrace the genera *Dermacoccus*, *Demetria* and *Kytococcus* (Stackebrandt and Schumann, 2000). The genus *Demetria* (Groth et al., 1997a) should be included because of its phylogenetic position and the presence of all 16S rDNA signature nucleotides as defined for the *Dermacoccaceae*.

DERMATOPHILACEAE The genus *Dermatophilus* contains the type species *D. congolensis* (Van Saceghem, 1915; Gordon, 1964), which was isolated from tissue specimens of infected mammals and lizards and identified as the cause of the skin disease streptotrichosis, and *D. chelonae* (Masters et al., 1995), which was isolated from

infected chelonids (turtles and a tortoise). Both *Dermatophilus* species produce branching filaments that divide by transverse and longitudinal septa to form zoospores. The zoospores form germ tubes, elongate into filaments and repeat the cycle. *D. chelonae* differs from *D. congolensis* in the formation of thin capsules around mature filaments (Masters et al., 1995). Phylogenetic analysis of the two species reveals only a moderate degree of relatedness (94.7%), and phylogenetic analysis including a varying selection of reference organisms does not consistently group them as phylogenetic neighbors.

Members of the genus show a directly cross-linked peptidoglycan with meso-A₂pm as diagnostic diamino acid (variation A1γ; Schleifer and Kandler, 1972). Cellular fatty acids of *D. congolensis* are of the straight-chain saturated type (R. M. Kroppenstedt, 1977; Table 7). Mycolic acids are absent. Because they were identified as causative organisms of streptotrichosis in mammals and reptiles and were also isolated from humans, both *Dermatophilus* species were affiliated to risk group 2.

DERMACOCCACEAE The description of the genera *Dermacoccus* and *Kytococcus* resulted from the taxonomic dissection of the genus *Micrococcus* (Cohn, 1872; Stackebrandt et al., 1995). These two genera, as well as *Demetria*, are characterized by the peptidoglycan variation A4α based on L-lysine (Schleifer and Kandler, 1972). No pathogenic potential has been reported for strains of these genera.

DERMOCOCCUS. The type species *D. nishinomiyaensis* (Oda, 1935; Skerman et al., 1980) of the genus *Dermacoccus* (Stackebrandt et al., 1995) was isolated from mammalian skin. Strains produce spherical cells occurring in pairs, tetrads

Table 8. Chemotaxonomic characteristics of the *Rarobacter*.

Genus	Diamino acid ^b	Interpeptide bridge ^b	Major menaquinone ^c	Predominant cellular fatty acids ^d	Mol% G+C
<i>Rarobacter</i>	L-Orn	Ser-Glu or Glu	MK-9	ai-C _{15:0} , i-C _{16:0} , C _{14:0} (aerobic)	65–66

Abbreviations: Orn, ornithine; refer to the footnotes in Tables 4 through 7 for definitions of all other abbreviations. Data are from reference Goto-Yamamoto et al., 1993.

Table 9. Chemotaxonomic characteristics of the *Sanguibacter*.

Genus	Diamino acid	Interpeptide bridge	Major menaquinone	Predominant cellular fatty acid(s)	Mol% G+C
<i>Sanguibacter</i>	L-Lys	Ser-D-Glu	MK-9(H ₄)	C _{16:0} , ai-C _{15:0} , C _{18:0}	69–70

Refer to the footnotes in Tables 4 through 7 for definitions of all abbreviations. Data are from references Fernández-Garayzábal et al., 1995 and Pascual et al., 1996.

or irregular clusters of tetrads. The peptidoglycan is cross-linked via interpeptide bridges consisting of one or two residues of L-serine and one of either D-glutamic acid alone or D-glutamic acid plus L-alanine (Table 7).

KYTOCOCCUS. The type species *K. sedentarius* (ZoBell and Upham, 1944; Skerman et al., 1980) of the genus *Kytococcus* (Stackebrandt et al., 1995) was isolated from human skin. Cells are spherical and usually occur in tetrads, which can be arranged in cubical packets. The genus is characterized by the unique combination of only nonhydrogenated menaquinones and a peptidoglycan interpeptide bridge consisting of two D-glutamic acid residues (Table 7).

DEMETRIA. The genus *Demetria* and its type species *D. terrigena* were described for a single strain isolated from compost soil (Groth et al., 1997a). Cells are irregular coccoid-to-rod shaped and occur singly, in pairs, short chains or irregular clusters. The combination of the peptidoglycan type A4 α (Schleifer and Kandler, 1972) and MK-8(H₄) as predominating menaquinone is rare and has so far only been reported for *Bogoriella caseilytica* (Groth et al., 1997).

RAROBACTERACEAE The genus *Rarobacter* (Yamamoto et al., 1988), containing the type species *R. faecitabidus* (Yamamoto et al., 1988) and *R. incanus* (Goto-Yamamoto et al., 1993), was assigned to the emended family *Cellulomonadaceae* (Stackebrandt et al., 1997) following phylogenetic analysis of 16S rDNA sequences. Members of the genus are yeast-lysing facultative anaerobic bacteria which require hemin or hemoproteins as essential factors for aerobic growth and carbon dioxide for anaerobic growth. *Rarobacter* cells adhere to and agglutinate yeast cells and subsequently lyse them to utilize the digested cells as nutrients. Several lytic enzymes have been identified, one of which recognizes mannose chains of mannoproteins (Shimoi et al., 1995). Strains of *R. faecitabidus* were isolated

from wastewater treatment systems of alcoholic beverage factories (Yamamoto et al., 1988). Species are considered nonpathogenic and they are characterized by the peptidoglycan variation A4 β with L-ornithine as diagnostic diamino acid (Schleifer and Kandler, 1972), unsaturated menaquinones with nine isoprenoid units and 12-methyltetradecanoic acid as the predominating cellular fatty acid. *Rarobacter faecitabidus* shows a peptidoglycan interpeptide bridge consisting of serine and glutamic acid, whereas serine is lacking in the cell wall of *R. incanus* (Goto-Yamamoto et al., 1993; Table 8). The latter species is also described to lack catalase activity. The cells are motile irregular pleomorphic rods. Recent 16S rDNA analyses indicated that *Rarobacter* should not be included in *Cellulomonadaceae* inasmuch as it forms an individual line of descent worthy of family status within the suborder *Micrococccineae* (Stackebrandt and Schumann, 2000).

SANGUIBACTERACEAE The genus *Sanguibacter* has been affiliated to the family *Intrasporangiaceae* on the basis of 16S rDNA sequence comparison and shared unique 16S rDNA nucleotides (Stackebrandt et al., 1997). *Sanguibacter* embraces the type species *S. keddiei* (Fernández-Garayzábal et al., 1995), *S. suarezii* (Fernández-Garayzábal et al., 1995) and *S. inulinus* (Pascual et al., 1996). Strains show the peptidoglycan variation A4 α -based on L-lysine (Schleifer and Kandler, 1972) with an interpeptide bridge consisting of serine and D-glutamic acid and a tetrahydrogenated menaquinone with nine isoprenoid units (Table 9). Cells are short irregular motile rods. All strains were isolated from bovine blood samples and were therefore allocated to risk group 2, indicating a moderate pathogenic potential. *Sanguibacter* species were differentiated by physiological tests and DNA-DNA hybridization (Pascual et al., 1996). The inclusion of new genera into the family *Intrasporangiaceae*

rangiaceae resulted in the exclusion of the genus *Sanguibacter* (Fig. 4) and a consequent redefinition of signature nucleotides for the emended family *Intrasporangiaceae* (Stackebrandt and Schumann, 2000).

JONESIACEAE This family has been described for the monospecific genus *Jonesia*. The species *J. denitrificans*, originally described as *Listeria denitrificans* (Prevot, 1961), clustered with members of *Cellulomonas* and *Promicromonospora* in early 16S rDNA-based phylogenetic studies (Rocourt et al., 1987), but the branching points of the *Jonesia* and *Promicromonospora* lineages were not stable in subsequent studies based on almost complete 16S rDNA molecules (Stackebrandt and Prauser, 1992b). Following extensive phylogenetic studies, *Jonesia* was excluded from the family *Cellulomonadaceae* (Rainey et al., 1995) and described as a family of *Micrococcineae* (Stackebrandt et al., 1997) on the basis of its well separated phylogenetic position. Thus, the rationale for keeping *Jonesia* within *Cellulomonadaceae* based on morphological and biochemical properties (Stackebrandt and Prauser, 1992b) became less significant once its isolated position within the actinomycete 16S rDNA tree (Fig. 4) was ascertained.

Jonesia denitrificans, isolated from boiled ox blood (Sohier et al., 1948), is characterized by typical coryneform morphology, i.e., straight to irregularly bent rods, forming hyphal or even mycelium-like structures that undergo fragmentation. Cells are motile by means of peritrichous flagella. Chemotaxonomically, cells are defined by a DNA G+C content of 57% (Seeliger and Jones, 1986), peptidoglycan of the Lys-Ser-D-Glu type (variation A4 α ; Fiedler and Seger, 1983), menaquinones of the MK-9 type (Collins et al., 1979), and the presence of an *N*-acetyl galactoseamine-substituted poly(ribitol phosphate) teichoic acid (Fiedler et al., 1984). *Jonesia denitrificans* is classified as a pathogenic organism (risk group 2).

PROMICROMONOSPORACEAE The genus *Promicromonospora* contains three species, one of which, *P. enterophila* (Jäger et al., 1983), is a member of the *Cellulomonas*/Oerskovia cluster, sharing 99.6% 16S rDNA similarity with *C. turbata* (Rainey et al., 1995). The other two species, the type *P. citrea* (Rainey et al., 1995) and *P. sukumoe* (Takahashi et al., 1987), are closely related (98.5% 16S rDNA sequence similarity; F. A. Rainey, E. Stackebrandt, P. Schumann and H. Prauser, unpublished observations) and form a separate lineage of family rank adjacent to members of *Cellulomonadaceae* and *Microbacteriaceae*.

These soil and compost inhabitants display a nocardioform life cycle that most closely resembles those of *Nocardia* and *Nocardioidea*. The hyphae of an extended substrate mycelium fragment into nonmotile elements of different shape and size, which subsequently may give rise to new mycelia. Aerial mycelium may be formed on some synthetic media (Shirling and Gottlieb, 1966) and also undergoes fragmentation.

Chemotaxonomically, authentic *Promicromonospora* species are characterized by a Lys-Ala-Glu (variation A4 α) peptidoglycan type (only *P. citrea* has been investigated; Evtushenko et al., 1984), menaquinone mainly of the MK-9(H₄) type (Collins and Jones, 1981), and major fatty acids 12-methyltetradecanoic acid (ai-C_{15:0}) and 13-methyl tetradecanoic acid (i-C_{15:0}; Andreyev et al., 1983). The G+C content of DNA ranges from 70 to 75 mol% (Evtushenko et al., 1984). Members of the genus can be rapidly identified by phage typing using a set of two phages that do not attack members of phylogenetically neighboring genera (Stackebrandt and Prauser, 1992b).

The species are classified as nonpathogens. The type strain of *P. sukumoe* produces an antibiotic called 7-hydro-8-methyl-pteroyl glutamyl-glutamic acid (Murata et al., 1987).

INTRASPORANGIACEAE The family *Intrasporangiaceae* (Stackebrandt et al., 1997), established on phylogenetic grounds, was initially defined to include the type genus *Intrasporangium* as well as *Terrabacter* (Stackebrandt et al., 1997) and the peripherally related genus *Sanguibacter* (Fernández-Garayzábal et al., 1995). The genera *Terracoccus* (Prauser et al., 1997) and *Janibacter* (Martin et al., 1997), described just after the establishment of the family *Intrasporangiaceae*, have to be included into this family because of correspondence in their signature nucleotides. The addition of new taxa into the family led to the exclusion of the genus *Sanguibacter* that, together with *Rarobacter*, formed a separate subline of descent within *Micrococcineae*. Consequently the set of signature nucleotides specific for the emended family *Intrasporangiaceae* was redefined (Table 4; Stackebrandt and Schumann, 2000).

All genera of the family are monospecific and form a rather heterogeneous group with respect to their phenotypic characteristics. Except for *Janibacter limosus*, all members of the family have in common the peptidoglycan type A3 γ (Schleifer and Kandler, 1972), variation A41.2 (*Deutsche Sammlung von Mikroorganismen und Zellkulturen* (DSMZ)–*Catalogue of Strains*, DSMZ–German Collection of Microorganisms, Braunschweig, Germany), which is based on LL-A2pm, a triglycine interpeptide bridge and a

Table 10. Chemotaxonomic characteristics of genera of the family *Intrasporangiaceae*.

Genus	Diamino acid	Interpeptide bridge	Menaquinone	Polar lipids	Predominant cellular fatty acid(s)	Mol% G+C

<i>Terrabacter</i>	LL-A ₂ pm	Gly ₃ ^a	MK-8(H ₄)	PE, PI, DPG, PL	i-C _{15:0} , i-C _{14:0} , i-C _{16:0}	70–73
<i>Terracoccus</i>	LL-A ₂ pm	Gly ₃ ^a	MK-8(H ₄)	PE, PI, PG, DPG	i-C _{15:0} , ai-C _{15:0} , C _{16:0}	73

Abbreviations: Gly, glycine; PIM, phosphatidylinositol mannosides; i-C_{15:0}, 13-methyltetradecanoic acid; and C_{17:1}, heptadecenoic acid. Refer to the footnotes in Tables 4 through 7 for definitions of all other abbreviations.

^aGlycine bound to glutamic acid at position 2 of peptide subunit.

Data are from Schleifer and Kandler, 1972; Kalakoutskii, 1989; Collins et al., 1989; Martin et al., 1997; Prauser et al., 1997; and Schumann et al., 1997.

glycine residue bound to the α -carboxyl group of D-glutamic acid. The occurrence of the peptidoglycan type A3 γ variation A41.2 is unique within the bacterial kingdom. All members are considered nonpathogenic to humans and other vertebrates.

INTRASPORANGIUM. *Intrasporangium calvum*, the type species of the genus *Intrasporangium*, was isolated as an airborne organism from a school dining room (Kalakoutskii et al., 1967). It forms a branching mycelium, which tends to break into irregular fragments, i.e., typically nocardioform. An aerial mycelium does not occur. Strains possess totally unsaturated menaquinone MK-8 instead of MK-8(H₄) which is the characteristic menaquinone of all other representatives of the family (Table 10).

TERRABACTER. *Terrabacter tumescens*, type species of the genus, was isolated from soil and forms irregular rods with tendency to extensive primary branching. Aerial mycelia are not produced. A typical coryneform rod-coccus growth cycle occurs during cultivation on complex media. Molecular analysis of the microbial composition of sludge revealed the occurrence of a high fraction of organisms closely related to *T. tumescens* (Christensson et al., 1998), and these organisms may be involved in the removal of phosphorous from sludge.

The taxonomic position of this organism has been controversial for a long time. First described as *Corynebacterium tumescens* (Jensen, 1934), it was then affiliated to the genus *Arthrobacter* as *Arthrobacter tumescens* (Conn and Dimmick, 1947) and later reclassified on chemotaxonomic grounds as *Pimelobacter tumescens* (Suzuki and Komagata, 1983). A 16S rRNA sequence comparison revealed that the organism occupies a separate line of descent warranting the generic status as type species of the genus *Terrabacter* (Collins et al., 1989).

TERRACOCUS. *Terracoccus luteus*, type species of the genus *Terracoccus*, was isolated from the water-soil interface of a duck pond (Prauser et al., 1997). Cells of the organism are

invariably coccoid and occur singly, in pairs or in small irregular clusters. *Terracoccus luteus* differs from *Intrasporangium calvum* and *Terrabacter tumescens* in its fatty acid profile with lower amounts of 14-methyl pentadecanoic acid (i-C_{16:0}) and higher amounts of ai-C_{15:0} (Prauser et al., 1997).

JANIBACTER. The type species *J. limosus* has been isolated from 1-year-old sludge of a wastewater treatment plant (Martin et al., 1997). Whereas the type strain (DSM 11140) exhibits a rod-coccus growth cycle, cells of a second strain (DSM 11141) are invariably coccoid. Strains are characterized by the directly cross-linked peptidoglycan type A1 γ (Schleifer and Kandler, 1972), based on meso-A₂pm. The cellular fatty acid profile of *J. limosus* differs from that of other genera of the family in containing high amounts of heptadecanoic (C_{17:0}) and heptadecenoic (C_{17:1}) acids (Table 10).

MICROCOCCEAE The family *Micrococcaceae* (Pribham, 1929) was emended on the basis of 16S rDNA/rRNA sequence-based phylogenetic clustering and circumscription by a set of family-specific 16S rDNA signature nucleotides (Stackebrandt et al., 1997). The emendation of this family was a consequence of preceding phylogenetic analyses (Koch et al., 1994; Koch et al., 1995; Stackebrandt et al., 1995) of members of the genera *Micrococcus* and *Arthrobacter*. The emended family *Micrococcaceae* contains the type genus *Micrococcus*, as well as the genera *Arthrobacter* (Koch et al., 1995), *Kocuria* (Stackebrandt et al., 1995), *Nesterenkonia* (Stackebrandt et al., 1995), *Renibacterium* (Sanders and Fryer, 1980), *Rothia* (Georg and Brown, 1967; Skerman et al., 1980), and *Stomatococcus* (Bergan and Kocur, 1982).

All genera of the family *Micrococcaceae* are characterized by the occurrence of L-lysine as diagnostic diamino acid of the peptidoglycan and predominance of iso- and anteiso-branched cellular fatty acids but differ markedly in the structures of their interpeptide bridges and in the

Table 11. Chemotaxonomic characteristics of genera of the family *Micrococcaceae*.

Genus	Diamino acid	Interpeptide bridge	Major menaquinone	Polar lipids	Predominant cellular fatty acid(s)	Mol% G+C
<i>Micrococcus</i>	L-Lys	Peptide subunit or D-Asp	MK-8, MK-8(H ₂)	DPG, PI, PG, PL, GL	ai-C _{15:0} , i-C _{15:0}	69–76
<i>Arthrobacter</i> , globiformis group	L-Lys	MCA _{var}	MK-9(H ₂)	DPG, PG, PI, DMDG	ai-C _{15:0} , i-C _{15:0} , i-C _{16:0}	61–66
<i>Arthrobacter</i> , nicotianae group	L-Lys	DCA _{var}	MK-8, MK-9	DPG, PG, PI, DMDG	ai-C _{15:0}	60–65
<i>Kocuria</i>	L-Lys	L-Ala ₃₋₄	MK-7(H ₂), MK-8(H ₂)	DPG, PG, (PI, PL, GL)	ai-C _{15:0} , ai-C _{17:0} , i-C _{16:0}	66–75
<i>Nesterenkonia</i>	L-Lys	Gly-L-Glu	MK-8, MK-9	DPG, PG, PI, PL, GL	ai-C _{15:0} , ai-C _{17:0} , i-C _{16:0}	70–72
<i>Renibacterium</i>	L-Lys	L-Ala-Gly ^f	MK-9, MK-10	DPG, GL	ai-C _{15:0} , ai-C _{17:0}	52–54
<i>Rothia</i>	L-Lys	L-Ala ₃	MK-7	DPG, PG	ai-C _{15:0} , ai-C _{17:0} , C _{16:0}	49–53
<i>Stomatococcus</i>	L-Lys	L-Ala, L-Ser or Gly	MK-7	DPG, PG	ai-C _{15:0} , i-C _{16:0} , C _{16:0}	56–60

Abbreviations: MCA, monocarboxylic amino acid; DCA, dicarboxylic amino acid; var, variable amino acid composition in the interpeptide bridge; DMDG, dimannosyldiacylglycerol. Refer to the footnotes in Tables 4, 5, 6, 7 and 10 for definitions of all other abbreviations.

^fD-Alanine amide is bound to glutamic acid at position 2 of the peptide subunit.

Data are from Schleifer and Kandler, 1972; Collins, 1982; Embley et al., 1983; Jones and Collins, 1986; Gerencser and Bowden, 1986; Stackebrandt et al., 1983; Schleifer, 1986; Fiedler and Draxl, 1986; and Stackebrandt et al., 1995.

composition of their menaquinone and polar lipid patterns (Table 11).

MICROCOCCUS. The genus *Micrococcus* (Cohn, 1872) was emended after taxonomic dissection resulting from phylogenetic and chemotaxonomic analyses (Stackebrandt et al., 1995). It now contains two species: *M. luteus* as type species and *M. lylae*. Because of its high DNA G+C content of about 74 mol%, *M. luteus* has been included as a Gram-positive representative in comparative evolutionary studies, e.g., on the sequences and structures of RNases P RNAs (Haas et al., 1996), the organization and codon usage of the streptomycin operon (Ohama et al., 1987), the spectinomycin operon (Ohama et al., 1989), and anticodon composition of tRNAs (Kano et al., 1991). The UV endonuclease (DNA glycosylase/abasic lyase) of *M. luteus* has been cloned and characterized (Piersen et al., 1995; Shiota and Nakayama, 1997), as has been the structural genes encoding essential components of the enzyme hexaprenyl diphosphate synthase (Shimizu et al., 1998), which is involved in the generation of hexaprenyl diphosphate (the precursor of the prenyl side chain of menaquinone).

Both *Micrococcus* species have coccoid morphology and can be differentiated by their different interpeptide bridges and menaquinone patterns: *M. luteus* has an interpeptide bridge (peptidoglycan variation A2) and predominantly menaquinone MK-8, whereas *M. lylae* contains a D-aspartic acid interpeptide bridge (peptidoglycan variation A4α) and MK-8(H₂) as major menaquinone (Schleifer and Kandler, 1972;

Stackebrandt et al., 1995). The primary habitat is mammalian skin. Although micrococci are considered nonpathogenic, the increasing number of reports on micrococci isolated from clinical specimens necessitates further studies on their role as opportunistic pathogens (Goodfellow, 1998). This applies also to the members of the genera *Kocuria*, *Dermacoccus*, *Kytococcus* and *Nesterenkonia*.

ARTHROBACTER. Strains belonging to *Arthrobacter* (Conn and Dimmick, 1947), later emended by Koch et al. (1995), show a rod-coccus growth cycle and fall at least into two groups as revealed early by chemotaxonomic studies (Minnikin et al., 1978; Collins and Jones, 1981; Collins and Kroppenstedt, 1983; Stackebrandt et al., 1983). The type species *A. globiformis* (Conn and Dimmick, 1947) represents the core of the first, the so-called “globiformis” group, while the second, the “nicotianae” group, is centered around the species *A. nicotianae*. The globiformis group is characterized by the presence of a peptidoglycan of the A3α variation (i.e., an interpeptide bridge made up of one to four residues of L-amino acids like L-alanine, L-threonine or L-serine; Schleifer and Kandler, 1972) and of a dihydrogenated menaquinone with nine isoprenoid units MK-9(H₂). The “nicotianae” group comprises organisms that have peptidoglycan variation A4α (i.e., an interpeptide bridge made up of a dicarboxylic amino acid like glutamic or aspartic; Schleifer and Kandler, 1972) and menaquinones that are completely unsaturated with eight to ten isoprenoid units.

Arthrobacter species were subdivided into the following groups based on the amino acid sequence of their peptidoglycan interpeptide bridges (Komagata and Suzuki, 1987):

I. Ser-Thr-Ala, *A. oxydans* (Sgueros, 1954; Skerman et al., 1980), *A. polychromogenes* (Schippers-Lammertse et al., 1963; Skerman et al., 1980).

II. Ala-Thr-Ala, *A. aurescens* (Phillips, 1953; Skerman et al., 1980), *A. ilicis* (Mandel et al., 1961; Collins et al., 1981a), *A. ureafaciens* (Krebs and Eggleston, 1939; Clark, 1955; Skerman et al., 1980), *A. histidinolovorans* (Adams, 1954; Skerman et al., 1980), *A. nicotinovorans* (Kodama et al., 1992).

III. Ala1-4, *A. globiformis*, *A. pascens* (Lochhead and Burton, 1953; Skerman et al., 1980), *A. ramosus* (Jensen, 1960; Skerman et al., 1980), *A. crystallopoietes* (Ensign and Rittenberg, 1963; Skerman et al., 1980).

IV. Ser-Ala2-3, *A. atrocyaneus* (Kuhn and Starr, 1960; Skerman et al., 1980).

V. Thr-Ala2, *A. citreus* (Sacks, 1954; Skerman et al., 1980).

VI. Ala-Glu, *A. nicotianae*, *A. creatinolyticus* (Hou et al., 1998), *A. uratoxydans* (Stackebrandt et al., 1983), *A. protophormiae* (Lysenko, 1959; Stackebrandt et al., 1983).

VII. Glu, *A. sulfureus* (Stackebrandt et al., 1983).

With two exceptions these groups are in good agreement with 16S rRNA sequence-based phylogenetic clustering: *A. crystallopoietes* represents a separate line of descent outside of group III and *A. sulfureus* clusters together with organisms of group VI despite its interpeptide bridge consisting solely of glutamic acid (Funke et al., 1996; Hou et al., 1998; Fig. 5). The species *A. agilis* (interpeptide bridge of Thr-Ala; Ali-Cohen, 1889), its comb. nov. (Koch et al., 1995a; Koch et al., 1995b), *A. woluwensis* (interpeptide bridge of D-Asp; Funke et al., 1996) and *A. cummingsii* (interpeptide bridge of Ser-Glu; Funke et al., 1996) can not be affiliated to any of these groups, and each of them represents an individual line of descent (Funke et al., 1996; Hou et al., 1998).

The following species cannot be affiliated because 16S rDNA sequence data are lacking: *A. mysorens* (Nand and Rao, 1972; Skerman et al., 1980) belonging to group VI on the basis of a Ala-Glu interpeptide bridge (Komagata and Suzuki, 1987) and *A. duodecadis* (Lochhead, 1958; Skerman et al., 1980).

Arthrobacter globiformis has been subjected to some molecular studies: the overexpression in *Escherichia coli* of an esterase which stereospecifically hydrolyzes the (+)-*trans* (1R,3R) stereoisomer of ethyl chrysanthemate, which is

Fig. 5. Phylogenetic relatedness among authentic species of the genus *Arthrobacter*, which have been subgrouped based on results of 16S rDNA analysis. Organisms, the names of which are displayed in the same color, exhibit the same peptidoglycan structure. Numbers within the dendrogram indicate the percentages of occurrence of the branching order in 500 bootstrapped trees (only values of 70 and above are shown). Sequences of species of other genera of the family *Micrococcaceae* served as a root. The scale bar represents 2 nucleotide substitutions per 100 nucleotides.

the acidic part of pyrethrin, a naturally occurring insecticidal compound (Nishizawa et al., 1995); the manganese-dependent dioxygenase, involved in the degradation of aromatic compounds (Boldt et al., 1995); and the cloning and sequencing of the inulin fructotransferase genes (Haraguchi et al., 1995) and genes for glucodextranase and endodextranase (T. Oguma et al., unpublished observation).

The following two species cannot be considered authentic members of the genus *Arthrobacter* because 16S rDNA analysis clusters them separately from members of this genus (B. J. Tindall, E. Stackebrandt and J. Swiderski, unpublished observation); the type strain of *A. viscosus* (Gasdorf et al., 1965; Skerman et al., 1980) DSM 7303 and strain DSM 7287 are identical and cluster with *Rhizobium* species. *Arthrobacter viscosus* DSM 20159, on the other hand, is closely related to *Bacillus simplex* and *B. maroccanus*. The type strain of *A. siderocapsulatus* (i.e., National Collection of Industrial and Marine Biology (NCIMB) 11286; Dubinina and

Zhdanov, 1975; Skerman et al., 1980) and strain NCIMB 11287 (= DSM 7286) are highly related and cluster with *Pseudomonas putida* and related species.

The following *Arthrobacter* species, originally affiliated to the genus on morphological grounds, have been reclassified following chemotaxonomic and phylogenetic analyses: *A. flavescens* (Lochhead, 1958; Skerman et al., 1980) as *Microbacterium flavescens* (Collins et al., 1983; Takeuchi and Hatano, 1998), *A. picolinophilus* (Tate and Ensign, 1974; Skerman et al., 1980) as *Rhodococcus erythropolis* (Koch et al., 1995a), *A. radiotolerans* (Yoshinaka et al., 1973; Skerman et al., 1980) as *Rubrobacter radiotolerans* (Suzuki et al., 1988), *A. simplex* (Jensen, 1934; Lochhead, 1957; Skerman et al., 1980) as *Nocardioides simplex* (O'Donnell et al., 1982), *A. terregens* (Lochhead and Burton, 1953; Skerman et al., 1980) as *Microbacterium terregens* (Collins et al., 1983; Takeuchi and Hatano, 1998), *A. tumescens* (Jensen, 1934; Conn and Dimmick, 1947; Skerman et al., 1980) as *Terrabacterium tumescens* (Collins et al., 1989), and *A. variabilis* (Müller, 1961; Skerman et al., 1980) as *Corynebacterium variabile* (Collins, 1987).

The species *A. cumminsii* and *A. woluwensis* are the only species of the genus isolated from clinical specimens (Funke et al., 1996) and consequently affiliated to risk group 2. *Arthrobacter creatinolyticus* was isolated from human urine (Hou et al., 1998), but this as well as all other species of the genus is regarded as nonpathogenic.

NESTERENKONIA. The genera *Nesterenkonia* and *Kocuria* were established simultaneously with the taxonomic dissection of the genus *Micrococcus* (Stackebrandt et al., 1995). *Nesterenkonia* (Stackebrandt et al., 1995) is monospecific, and its coccoid type species is *N. halobia* (Onishi and Kamekura, 1972; Skerman et al., 1980). The moderately halophilic organism was isolated from unrefined solar salt (Onishi and Kamekura, 1972) and is characterized by a Gly-L-Glu interpeptide bridge of the peptidoglycan and by completely unsaturated menaquinones with eight or nine isoprenoid units (Table 11).

KOCURIA. The genus *Kocuria* (Stackebrandt et al., 1995) comprises five species: the type species *K. rosea* (Fluegge, 1896; Skerman et al., 1980), isolated from soil and water; *K. varians* (Migula, 1900; Skerman et al., 1980), isolated from mammalian skin, soil and water; *K. kristinae* (Kloos et al., 1974; Skerman et al., 1980), isolated from healthy human skin; *K. palustris* (Kovács et al., 1999) and *K. rhizophila* (Kovács et al., 1999), both isolated from the rhizosphere of *Typha angustifolia*. The species *K. erythromyxa* (Brooks and Murray, 1981; Rainey et al., 1997) has recently been transferred to *K. rosea*

(Schumann et al., 1999). All species of the genus *Kocuria* have in common a peptidoglycan interpeptide bridge, which consists of three to four alanine residues (Table 11).

STOMATOCOCCUS. This genus is monospecific, and the type species *S. mucilaginosus* (Bergan and Kocur, 1982) was isolated from the human oral cavity and the upper respiratory tract. The genus accommodates facultatively anaerobic cocci, which are characterized by a single L-alanine, L-serine or glycine residue as interpeptide bridge of their peptidoglycan and by a completely unsaturated menaquinone with seven isoprenoid units (Table 11). *Stomatococcus mucilaginosus* has been isolated in several cases from blood cultures taken mainly from immunocompromised patients (Goodfellow, 1998) and has been classified as a risk group 2 organism.

ROTHIA. The genus *Rothia* (Georg and Brown, 1967; Skerman et al., 1980) is monospecific, and the type species *R. dentocariosa* (Onishi, 1949; Skerman et al., 1980) is a normal inhabitant of the human oral cavity, most frequently isolated from supragingival dental plaque. *Rothia dentocariosa* is facultatively anaerobic, and the culture usually consists of cocci, irregular rods, and filaments. Strains possess an interpeptide bridge consisting of three alanine residues resembling that of *Kocuria* species, but differ from these species in their low G+C content of only 49–53 mol% and in the occurrence of the completely unsaturated menaquinone with seven isoprenoid units (Table 11). Although classified as a nonpathogenic organism, *R. dentocariosa* has been identified as the causative agent of pneumonia and septicemia in immunocompromised patients and it has been isolated from various inflammatory processes (Schaal, 1992).

RENIBACTERIUM. The type species of the monospecific genus, *R. salmoninarum* (Sanders and Fryer, 1980), is an obligate pathogen of salmonid fish. It usually causes a chronic, systemic, granulomatous infection of the kidney, which can be fatal for the fish under appropriate conditions (Evelyn, 1993). Based upon multilocus enzyme electrophoresis and analysis of the intergenic spacer region between 16 and 23S rRNA genes, recent epidemiological studies on *R. salmoninarum* isolates from a broad variety of fish from different locations indicated a low level of genetic diversity (Starliper, 1996; Grayson et al., 1999), although random amplified polymorphic DNA (RAPD) analysis allowed reproducible differentiation between isolates obtained from different hosts and different geographic regions. Possible virulence factors of *R. salmoninarum* have been sought by screening a genomic library for expression of virulence factors in *E. coli*. A single hemolytic clone was identified and

the gene encoded resembled that of bacterial zinc-metalloproteases (Grayson et al., 1995). Additional information is available for the gene coding for the 57-kDa major soluble antigen (Chien et al., 1992).

The slowly growing cells occur as short regular rods often in pairs and sometimes in short chains. *Renibacterium salmoninarum* is characterized by a peptidoglycan with an L-alanine-glycine interpeptide bridge and D-alanine amide bound to D-glutamic acid at position 2 of the peptide subunit, by completely unsaturated menaquinones with nine and ten isoprenoid units and by a low G+C value of 52–54 mol% (Table 11). Because of its potential pathogenicity for salmonid fish, *R. salmoninarum* is allocated to risk group 2.

The Family Bifidobacteriaceae

BRUNO BIAVATI AND PAOLA MATTARELLI

Family Bifidobacteriaceae

Family Bifidobacteriaceae fam. nov., Stackebrandt, Rainey and Ward-Rainey. Bifidobacteriaceae (Bi.fi.do.bac.teri.a'ce.ae. ending to denote a family; M.L. fem. pl. n. Bifidobacteriaceae, the Bifidobacterium family). The pattern of 16S rDNA signatures consists of nucleotides at positions 122-239 (G-U), 128-233 (C-G), 450-483 (C-G), 602-636 (C-G), 681-709 (C-G), 688-699 (A-U), 823-877 (A-U), 1118-1155 (C-G) and 1311-1326 (A-U; Stackebrandt et al., 1997).

The family contains the type genus *Bifidobacterium* (Orla-Jensen, 1924) with 32 species (type species *Bifidobacterium bifidum*, Tissier; Orla-Jensen, 1924) as well as *Gardnerella* (Greenwood and Pickett, 1980) with *Gardnerella vaginalis* as the only species. A phylogenetic structure of the genera *Bifidobacterium* and *Gardnerella* has been published (Maidak et al., 1994; Leblond-Bourget et al., 1996).

Characteristics of the Family

The family consists of pleomorphic rods that occur singly or in many-celled chains or clumps. Cells have no capsule and they are nonspore-forming, nonmotile, and nonfilamentous. They are Gram positive except for *G. vaginalis*, which is Gram variable. They are anaerobic (some *Bifidobacterium* species can tolerate O₂ only in presence of CO₂) or facultatively anaerobic (*Gardnerella*). They are negative for the following: indole, gelatin hydrolysis, catalase (except for *B. indicum* and *B. asteroides* when grown in presence of air), and oxidase. Optimum growth temperature is 35–39°C. They possess fructose-6-phosphoketolase (EC 4.1.2.2), which cleaves fructose-6-phosphate into acetylphosphate and erythrose-4-phosphate. The G+C content varies from 42–67 mol%. They are chemoorganotrophs having a fermentative type of metabolism. They produce acid but no gas from a variety of carbohydrates. They occur in animal and human habitats. They are nonpathogenic except for

bifidobacteria isolated from dental caries (and probably involved in caries pathology) and for *G. vaginalis* that often assumes pathogenic character (such as in bacterial vaginosis and in urogenital tract infections of both sexes).

Genus *Bifidobacterium*

Phylogeny

Tissier discovered bifidobacteria in infant feces and called them “*Bacillus bifidus*” (Tissier, 1899; Tissier, 1900). In 1924, Orla-Jensen recognized the existence of the genus *Bifidobacterium* as a separate taxon, but given their similarities to the genus *Lactobacillus*, bifidobacteria were included in the genus *Lactobacillus* as listed in the seventh edition of *Bergey's Manual of Determinative Bacteriology* (Breed et al., 1957).

In the eighth edition of *Bergey's Manual of Determinative Bacteriology* (Buchanan et al., 1974) bifidobacteria were classified in the genus *Bifidobacterium*, the name initially adopted by Orla-Jensen. The genus comprised eight species and was included in the family Actinomycetaceae of the order Actinomycetales of the Actinomycetes and related organisms, although with regard to the murein structure of the cell wall, bifidobacteria are more similar to Lactobacillaceae than to Actinomycetaceae (Kandler and Lauer, 1974).

The introduction of rRNA gene sequence analysis in studies on the phylogeny of bacteria has confirmed the assignment of bifidobacteria to an “Actinomyces” group (Fox et al., 1980).

In the first edition of *Bergey's Manual Systematic Bacteriology* (Sneath et al., 1986), as well as the ninth edition of *Bergey's Manual of Determinative Bacteriology* (Holt et al., 1993), organisms of the genus *Bifidobacterium* were grouped and defined as “irregular, nonsporing, gram-positive rods.” The rRNA sequence analysis was mostly used to determine relationships among genera, families and other ranks. Molecular phylogeny, derived from high correlation of several molecules (e.g., 16S RNA genes coding for 16S rRNA

or 16S rDNA; Woese, 1987), 23S rDNA (Collins and Wallbanks, 1992), elongation factors involved in translation, and the β -subunit of ATPase (Ludwig et al., 1993), led to the description of domains for the three highest taxa: Archaea, Bacteria and Eukarya (Woese et al., 1990). Stackebrandt et al. (1997), through 16S rDNA analysis, proposed a novel hierarchical structure for the phylogenetic group of "Actinomycetes, bacteria and relatives." This proposal does not change the current description of species and genera based upon morphological, chemotaxonomic and physiological characters but "provides the descriptions of taxa above the genus level incorporating the characteristics of the individual genera contained therein." The genus *Bifidobacterium* together with the genus *Gardnerella* has been collected into the single family of Bifidobacteriaceae in the order of Bifidobacteriales in the subclass of Actinobacteridae in the class of Actinobacteria in the lineage of Firmicutes and in the domain of Bacteria (Stackebrandt et al., 1997; Fig. 1).

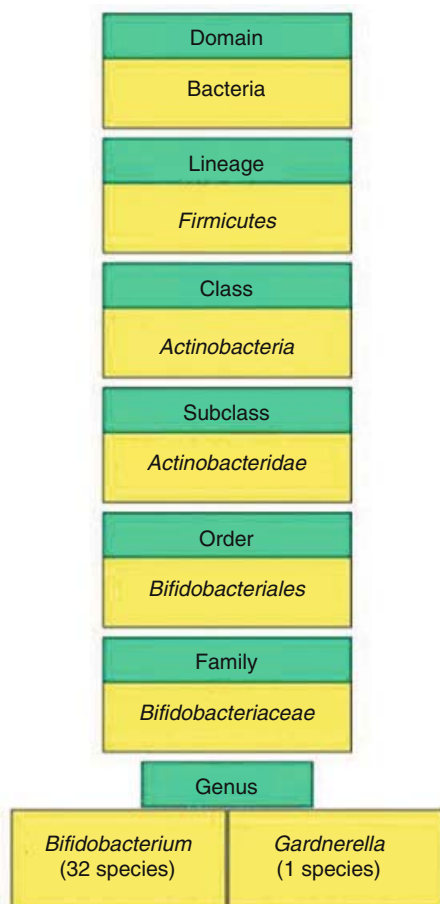

Fig. 1. Phylogeny of the genera *Bifidobacterium* and *Gardnerella*.

Taxonomy

Bifidobacteria were first discovered by Tissier, who observed and isolated a bacterium with a strange and characteristic Y shape in the feces of breast-fed infants. This bacterium was anaerobic, Gram-positive and did not produce gas during its growth (Tissier, 1899). Because of this morphology, he termed this organism "*Bacillus bifidus*" (Tissier, 1900). Winslow et al. (1917) proposed the family Lactobacillaceae, and three years later, Holland (1920) named the Tissier strain *Lactobacillus bifidus*.

During what Poupard et al. (1973) call the "first period" in the history of these bacteria, namely from 1900 to 1957, few advances were made in the knowledge of their biochemistry and taxonomy. In the seventh edition of *Bergey's Manual of Determinative Bacteriology* (Breed et al., 1957), only *Lactobacillus bifidus* was reported, although in 1924 Orla-Jensen had already recognized the existence of the genus *Bifidobacterium* as a separate taxon (Orla-Jensen, 1924).

In 1957, Dehnert first recognized the existence of multiple biotypes of *Bifidobacterium* and proposed a scheme for the differentiation of five groups of these bacteria based on their carbohydrate fermentation patterns (Dehnert, 1957). Reuter (1963) recognized and named seven species of *Bifidobacterium*, in addition to the known *B. bifidum*, on the basis of fermentative and serological characters and presented a scheme for their identification. The species of Reuter's scheme were: *B. bifidum* var. *a* and *b*; *B. infantis*; *B. parvulorum* var. *a* and *b*; *B. breve* var. *a* and *b*; *B. liberorum*; *B. lactentis*; *B. adolescentis* var. *a*, *b*, *c* and *d*; and *B. longum* var. *a* and *b*. The next major classification scheme was presented by Mitsuoka (1969). In this scheme, new fermentative biotypes added to *B. longum* species (*B. longum* subsp. *animalis a* and *b*) and two new species, *B. thermophilum* and *B. pseudolongum*, found in the feces of a variety of animals (e.g., pigs, chickens, calves and rats) were included. In the same year, Scardovi et al. (1969b) isolated *B. ruminale* (synonym of *B. thermophilum*) and *B. globosum* from cattle rumen. Furthermore, Scardovi and Trovatielli (1969a) found *B. asteroides*, *B. indicum* and *B. coryneforme* in the intestine of honeybees, three new species morphologically quite different from the previously known bifidobacteria (see Fig. 2).

Twenty-four species of the genus *Bifidobacterium* are listed in the first edition of *Bergey's Manual of Systematic Bacteriology* (Scardovi, 1986). This marked expansion of the genus was based on significant contributions of Biavati et al. (1982), Dehnert (1957), Matteuzzi et al. (1971), Mitsuoka (1969), Reuter (1963),

Phase-contrast photomicrographs show (1) *B. adolescentis*, (2) *B. angulatum*, (3) *B. animalis*, (4) *B. asteroides*, (5) *B. bifidum*, (6) *B. boum*, (7) *B. breve*, (8) *B. catenulatum*, (9) *B. choerinum*, (10) *B. coryneforme*, (11) *B. cuniculi*, and (12) *B. denticolens*.

Fig. 2. Panels 13–24 show (13) *B. dentium*, (14) *B. infantis*, (15) *B. gallicum*, (16) *B. gallinarum*, (17) *B. indicum*, (18) *B. inopinatum*, (19) *B. lactis*, (20) *B. longum*, (21) *B. magnum*, (22) *B. merycicum*, (23) *B. minimum*, and (24) *B. pseudocatenulatum*.

Fig. 2. Panels 25–32 show (25a) *B. pseudolongum* subsp. *pseudolongum*, (25b) *B. pseudolongum* subsp. *globosum*, (26) *B. pullorum*, (27) *B. ruminantium*, (28) *B. saeculare*, (29) *B. subtile*, (30) *B. suis*, (31) *B. thermophilum*, and (32) a scanning electron micrograph of *Bifidobacterium* spp. (Reproduced with permission from V. Bottazzi, Università Cattolica del Sacro Cuore, Piacenza, Italy.)

Scardovi and Crociani (1974a), Scardovi and Trovatelli (Scardovi and Trovatelli, 1969a; Scardovi and Trovatelli, 1974b), Scardovi and Zani (1974c), Scardovi et al. (Scardovi et al., 1971b; Scardovi et al., 1979b) and Trovatelli et al. (1974). Afterwards, the description of eight additional species and the description of *B. globosum* as subspecies of *B. pseudolongum* (Yaeshima et al., 1992) were introduced: *B. gallicum* isolated from human feces (Lauer, 1990), *B. merycicum* and *B. ruminantium* isolated from rumen of cattle (Biavati and Mattarelli, 1991), *B. saeculare* isolated from rabbit feces (Biavati et al., 1991a), *B. denticolens* and *B. inopinatum* both isolated from dental caries (Crociani et al., 1996b), *B. lactis*

isolated from yogurt (Meile et al., 1997), and *B. thermacidophilum* isolated from anaerobic digesters (Dong et al., 2000). The habitat and type strain of each species are listed in Table 1.

The pathway of hexose fermentation in bifidobacteria has, in the meantime, been elucidated by radioactive-carbon distribution and assay of enzymes in cellular extracts by Scardovi and Trovatelli (1965) and De Vries et al. (1967). The key enzyme (fructose-6-phosphate phosphoketolase [F-6-PPK]) of this pathway (the fructose-6-phosphate shunt; Fig. 3), purified later by Sgorbati et al. (1976), splits hexose phosphate to erythrose-4-phosphate and acetyl phosphate (Schramm et al., 1958). From tetrose and hexose phosphates, through the successive action of

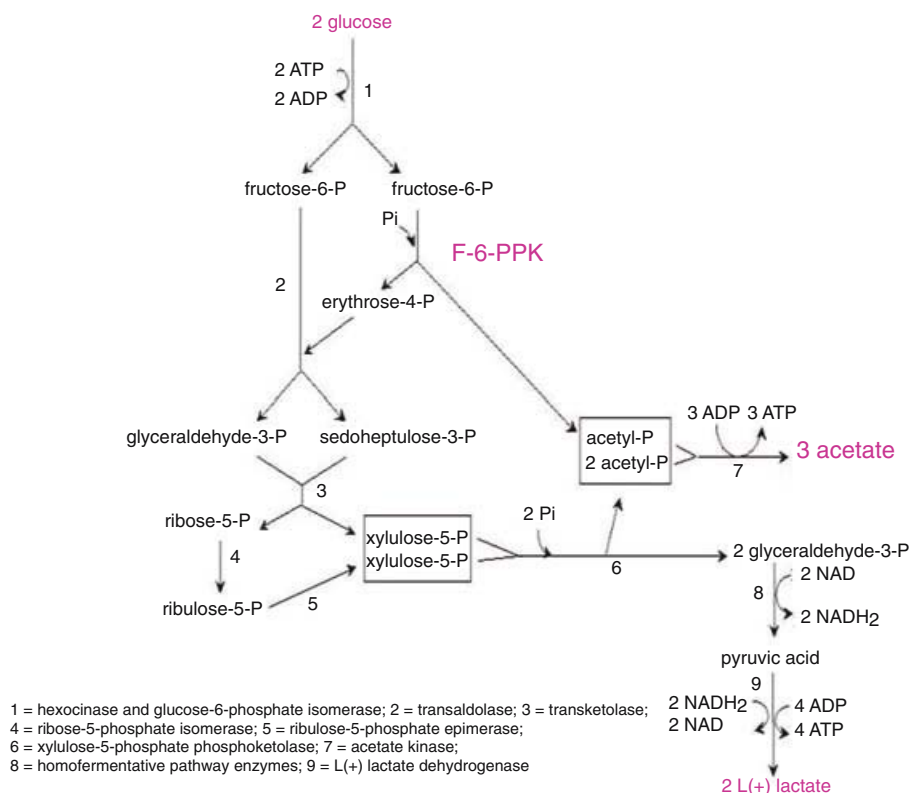

Fig. 3. Hexose metabolic pathways in *Bifidobacterium*.

transaldolase and transketolase, pentose phosphates are formed that, via the usual 2–3 cleavage, give rise to lactic acid and acetic acid so that lactic and acetic acids are formed in the theoretical ratio 1.0:1.5.

Phosphoroclastic cleavage of some pyruvate to formic and acetic acids and reduction of acetate to ethanol can often alter the fermentation balance (De Vries and Stouthamer, 1968) to a highly variable extent (Lauer and Kandler, 1976). During the metabolism of hexoses, there is no production of carbon dioxide, except in the degradation of gluconate.

Recently the presence of F-6-PPK has been found in *Gardnerella vaginalis* (Gavini et al., 1996). The genera *Gardnerella* and *Bifidobacterium* are phylogenetically very similar (Embley and Stackebrandt, 1994) but can be easily distinguished on a phenotypic basis. The guanine and cytosine (G+C) content of DNA is quite high (55–67 mol%), with differences among species (Scardovi, 1986; Table 2). The only exception is *B. inopinatum*, one of the three species found in dental caries, with a G+C mol% of 45 (Crociani et al., 1996b).

In 1970, Scardovi and colleagues started to extensively apply the DNA-DNA filter hybridization procedure to assess the validity of the bifidobacterial species previously described

(Scardovi et al., 1970; Scardovi et al., 1971b) and to recognize new DNA homology groups among the strains they were isolating in large numbers from diverse ecological niches, such as the feces of humans and animals, the rumen of cattle, sewage, the human vagina, dental caries and honeybee intestine (see Table 1). Some emendations of Reuter and Mitsuoka's species identifications were suggested (Scardovi et al., 1971b) and accepted (Rogosa, 1974). *Bifidobacterium liberorum* and *B. lactentis*, for example, were proposed as synonyms of *B. infantis*, and *B. parvulum* was proposed as a synonym of *B. breve*, *B. longum* subsp. *animalis*. Mitsuoka was elevated to the species rank as *B. animalis* (Scardovi and Trovatielli, 1974b). Four additional species isolated from animal feces were described and proposed in 1979: *B. pseudocatenulatum*, *B. boum*, *B. choerinum*, and *B. cuniculi* (Scardovi et al., 1979b).

In 1982, the use of polyacrylamide gel electrophoresis (PAGE) of soluble cellular proteins was first introduced to distinguish species of bifidobacteria (Biavati et al., 1982). More than 1,000 strains of bifidobacteria were characterized using this technique. An excellent correlation with the data obtained through DNA-DNA homology was found. One of the results of this work was the proposal for the reinstatement of *B. coryneforme* (Scardovi and Trovatielli, 1969a) and *B.*

^aAmino acid in parentheses occasionally replaces the preceding amino acid; data from Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH (DSMZ; German collection of microorganisms and cell cultures).

^bAverage values; data from Scardovi (1986); for the values of the recently described species see under single species description.

^cNumbers 1–10 and 1–13 were given to isozymes of transaldolase and 6-phospho-D-gluconate dehydrogenase: NAD(P)oxido-reductase (6PGD), respectively, in the order of decreasing mobility (subscripts indicate additional isozymes). Boldface numbers are the isozymes of the type strains. Numbers in parentheses are isozymes found in less than 10% of the strains studied. The 6PGD is undetectable by spot staining in most strains of *B. dentium* and in all strains of *B. pullorum*. “Present” and “Absent” indicate presence and absence as determined by other methods. Data from Scardovi et al. (1979a).

globosum (Scardovi et al., 1969b), which had not appeared in the Approved Lists of Bacterial Names (Skerman et al., 1980). Moreover, *B. minimum* and *B. subtile* homology groups (Scardovi and Trovatielli, 1974b) were elevated to the species level.

A study of DNA-DNA homology and several phenotypic characteristics of the type strains of *Bifidobacterium* spp. was done by Lauer and Kandler (1983). On the basis of their data, they

suggested that the three species *B. longum*, *B. suis* and *B. infantis* be merged into only one species, namely *B. longum*; that *B. pseudocatenulatum* and *B. catenulatum* be recognized as two subspecies rather than two species; and that *B. pseudolongum* be merged into *B. globosum*, and *B. indicum* into *B. coryneforme*. The fact that some species of the genus *Bifidobacterium* are closely related is well established. However, when all the data available from the large

^aElectrophoretic patterns of enzymes taken from Scardovi et al. (1979a). Numbers were given to isozymes of phosphogluconate dehydrogenase and transaldolase in order of decreasing anodic mobility (numbers with subscript letters indicate additional isozymes). Numbers in boldface are the isozymes of the type strains. Numbers in parentheses are isozymes found in less than 10% of strains. The enzyme phosphogluconate dehydrogenase is undetectable by spot staining in most strains of *B. dentium* and in all strains of *B. pullorum*. The lines indicate which reactions are useful as characteristic markers.

Fig. 4. Key for differentiation of *Bifidobacterium* species of human origin.

number of strains studied are considered, the presence of different characters emerges, justifying the present separation scheme (Scardovi, 1986). To this day, only *B. globosum* has been merged with *B. pseudolongum* and has been described as a subspecies of *B. pseudolongum* (Yaeshima et al., 1992). A key for the identification of the species based on isoenzyme patterns and fermentation tests (so far described only in the second edition of *The Prokaryotes*; Biavati et al., 1991b) is presented in Table 3. A new identification key for human bifidobacteria based on complex carbohydrates and mucin fermentation has been introduced by Crociani et al. (Crociani et al., 1994; Fig. 4).

A study on rRNA sequences at the end of the 1970s provided a key to prokaryote phylogeny (Fox et al., 1980). The introduction of 16S rRNA/DNA sequence analysis, better than any other taxonomic method, placed an organism in the framework of phylogenetic relationships. This brought about the “molecular revolution” that led to the reorganization of the taxonomy above the genus level. Because of this, the genera *Gardnerella* and *Bifidobacterium* have been included in one family, Bifidobacteriaceae (Stackebrandt et al., 1997).

Milestones in the *Bifidobacterium* taxonomy are reported in Fig. 5.

Habitat

The presence of bifidobacteria in the alimentary tracts of human adults and infants has stimulated much interest among bacteriologists and nutritionists. Many factors control the number and the composition of microbial populations in dif-

ferent regions of the gastrointestinal tract. The ways of restoring or maintaining a proper microbial balance have been extensively investigated (see “Applications”). In the intestinal tract of animals and humans, bifidobacteria coexist with a large variety of bacteria, most of which are obligate anaerobes; components of this microflora are different in the different areas of the tract (Moore et al., 1969). The obligate anaerobes of this complex microflora are in part unknown at present, although significant advances have been made in recent times with the appropriate techniques of identification such as molecular probes. Furthermore, if one considers that particular ecotypes (or biovars) probably have more ecological significance in these habitats than do the species to which they belong (Benno and Mitsuoka, 1986; Mitsuoka, 1972; Mitsuoka, 1984; Sears and Brownlee, 1952; Sears et al., 1950), all factors that pertain to and influence natural genetic variation of single bacterial populations should be studied (Milkman, 1975).

In studies on the ecology of bifidobacteria performed at the Institute of Agricultural Microbiology at Bologna University, Italy, a large number of strains (at present more than 7,000) has been isolated from many different habitats (see Table 1). Studies on the distribution of bifidobacteria in feces of both infants (Biavati et al., 1984) and adults (Biavati et al., 1986), the human vagina (Crociani et al., 1973), or “pathological conditions” such as dental caries (Crociani et al., 1996b) and hypochlorhydria (Brandi et al., 1996) point out that the adaptations of the species of human origin to the five habitats (Fig. 6) are different. *Bifidobacterium bifidum* and *B. longum*, for example, are the most represented species in the intestinal tract of infants and adults, whereas the group “*B. denticolens*, *B. inopinatum* and *B. dentium*” is typical of dental caries and hypochlorhydric stomach. *Bifidobacterium ado-*

lescentis, *B. bifidum*, *B. longum* and *B. breve* are typically found in the vagina.

Furthermore, bifidobacteria have been isolated from many animals and, among insects, from honeybees. In general, *Bifidobacterium* species are specific either for humans or for animals; the same *Bifidobacterium* species found in the intestinal microflora of suckling calves and breast-fed infants is the exception. Some species,

12 out of 16, are host-specific, and they are typical of a given animal habitat (Fig. 7).

Eleven species of *Bifidobacterium* have been found in sewage (Fig. 8): 5 are from humans, 4 are from animals, and *B. minimum* and *B. subtile* are found only in sewage. This raises the exciting question of the possible development of bifidobacteria in extraenteral ecological niches. *Bifidobacterium lactis*, a new species recently described by Meile et al. (1997), was isolated from yogurt, but this cannot be considered an *extra-body* habitat because these bifidobacteria are added to yogurt because of their probiotic properties. *Bifidobacterium thermacidophilum* is the most recently described species, described by Dong et al. (2000), and has been isolated from an

anaerobic digester used to treat wastewater from a bean-curd farm. This species differed from other species of *Bifidobacterium* by its growth at temperature of 49.5°C and by its ability to grow in medium with the starting pH of 4.0.

The habitats from which bifidobacteria were isolated are shown in Fig. 9.

Isolation

Many media have been devised for isolating or enumerating the bifidobacteria. They can be divided into nonselective and selective media.

NONSELECTIVE MEDIA The most frequently used nonselective media are described in Table 4. Preliminary trials made with bifidobacteria from human feces, bovine rumen, and honeybee intestine showed that the ingredients ensuring their maintenance in stab cultures were trypticase and phytone (BBL). Finally, the following medium was adopted, which allowed for the isolation and cultivation of strains belonging to widely different genetic species of *Bifidobacterium* from all the habitats so far investigated.

Trypticase-Phytone-Yeast Extract (TPY) Medium

The medium contains per liter:

Trypticase (BBL)	10 g
Phytone (BBL)	5.0 g
Glucose	15 g
Yeast extract (Difco)	2.5 g
Tween 80	1 ml
Cysteine hydrochloride	0.5 g
K ₂ HPO ₄	2.0 g
MgCl ₂ · 6H ₂ O	0.5 g

Final pH is about 6.5 after autoclaving at 110°C for 30 min. Dilution can be made in the same medium. Vented Petri dishes are incubated at 37°C anaerobically. After 3–4 days of incubation, colonies are transferred into stab cultures or TPY medium with 0.5 % agar. After growth has occurred on stabs, these are stored at 3–4°C in an anaerobic jar. Transfer should be made every 2–3 weeks. The same liquid medium is used for the cultivation of bifidobacteria. Any size of tube or flask can be used as long as anaerobic conditions are respected and temperature controlled.

Because the medium is not selective, streptococci, lactobacilli, and other forms may grow profusely. Because bifidobacterial colonies cannot be differentiated from nonbifid ones, all morphological types grown on plates should be scored and tested as indicated in the section on identification.

SELECTIVE MEDIA To improve selectivity, antibiotics and other factors inhibiting the growth of contaminant microorganisms are used (lithium chloride, sodium propionate or propionic acid, low pH [such as 5 or 5.5], iodoacetic acid, etc.), as well as factor components which improve the growth of bifidobacteria (riboflavin, nitrogenous bases and pyruvic acid, simple or complex carbohydrates such as raffinose, lactose, lactulose, oligosaccharides, etc.).

The selective substrates mainly used are listed in Table 4. In some cases, the use of selective media can be very helpful, but owing to great intraspecific variation in the resistance of bifidobacteria to antibiotics (Matteuzzi et al., 1983) or in their utilization of elective substances (Cro-

ciani et al., 1994), the media proposed neither guarantee complete selectivity nor allow the growth of all the species of bifidobacteria. Rather, these media permit satisfactory growth of the largest number of bifidobacterial types presently known. There is no general recipe; therefore, the choice of substrate and level of selectivity are suggested by the type of sample: for the media used to determine bifidobacteria counts in dairy products, for example, the presence of substances inhibiting dairy bacteria (such as lactobacilli and streptococci) is important.

In our experience the slightly modified medium proposed by Beerens (1990), which includes TPY instead of Columbia medium, can be very useful for isolation from both feces and dairy product samples.

Identification

Identification of a bacterial strain as *Bifidobacterium* is difficult. The morphology is of little help in identifying an isolate as a *Bifidobacterium*, but of great help in the recognition of a bifidobacterial species. Some morphological traits, such as disposition and number of branches, cell contours, dimensions, and arrangement in groups, are typical of many known *Bifidobacterium* species grown in solid TPY medium. Therefore, the morphologies illustrated in Fig. 2 (panels 1–31)

are useful for species differentiation. Cultural and physiological characters are grossly shared by many other genera, e.g., *Actinomyces*, *Corynebacterium* and *Lactobacillus*. One of the more practical approaches to the primary differentiation of bifidobacteria from related groups is the one proposed by Holdeman et al. (1977), which is based on identification by gas chromatography of the fermentation products, among which acetic acid generally predominates over lactic acid as the main final product. Side reactions, however, can lead to formation of substantial and variable amounts of ethanol and of formic and succinic acids, so that the pattern can be difficult to interpret, especially for the inexperienced worker. The most direct and reliable assignment of a bacterial strain to the genus *Bifidobacterium* is the one based upon the demonstration (in cellular extracts) of fructose-6-phosphate phosphoketolase, the key enzyme of bifidobacterial hexose metabolism (Fig. 3). Its validity is not only dictated by the results of previous investigation (De Vries et al., 1967; Scardovi and Trovatielli, 1965), but is confirmed with organisms isolated from the most diverse habitats.

Although DNA-DNA hybridization remains one of the more valuable tests in the identification of *Bifidobacterium* species, it cannot be routinely carried out in most laboratories. Iden-

tification of *Bifidobacterium* species, however, can be achieved with the use of the fermentation tests (particularly complex carbohydrate fermentations are useful for differentiation of human species; see Fig. 4) and/or cell-wall structure type and/or electrophoretic tests of cellular proteins.

In the last few years, certain molecular techniques based on sequence comparisons of DNA or RNA have been developed that provide the genus or species or strain characterization as well as a classification scheme that predicts natural evolutionary relations. Techniques which allow phylogenetic and typing characterization of intestinal microflora include 16S rRNA sequence analysis, rec A and internal transcribed spacer (ITS) sequence analysis; techniques for monitoring the distribution and prevalence of specific microbes include colony hybridization with nucleic acid probes, pulsed-field gel electrophoresis (PFGE), ribotyping, restriction fragment length polymorphism (RFLP) of the 16S rRNA gene and random amplified polymorphic DNA (RAPD). The use of such molecular techniques to analyze microflora is an additional aid to advancement of intestinal microflora complexity studies. In the future, the impact of such approaches on the study of this intestinal niche will be fundamental, and such studies may provide a scientific basis for application of potential probiotic bacteria to the maintenance of intestinal health. Such molecular techniques are not yet universally applicable to all species of *Bifidobacterium* genus; it is therefore important to develop further these applications. The DNA-DNA homology technique remains the most reliable method to identify the *Bifidobacterium* species.

The most common techniques for the identification of *Bifidobacterium* genus, species or strain are shown in Fig. 10. Procedures routinely performed in our laboratories are described in this chapter. For more detailed information please contact the authors.

PHENOTYPIC IDENTIFICATION

Genus Identification Fructose-6-phosphate phosphoketolase (F-6-PPK) is present in all bifidobacterial species and to this day the F-6-PPK assay (Scardovi and Trovatelli, 1969a) is the test that allows a strain to be identified reliably as a *Bifidobacterium* sp. This enzyme is present in *Gardnerella vaginalis* as well, but the genera *Gardnerella* and *Bifidobacterium* can be easily distinguished phenotypically. Fructose-6-phosphate phosphoketolase is involved in the breakdown of fructose-6-phosphate to erythrose-4-phosphate and acetyl phosphate in the presence of inorganic phosphate (Fig. 3); sodium pyrophosphate, ATP and ADP are mod-

ulators of its activity, whereas copper (Cu^{++}) ions, *p*-chloromercuribenzoic acid (*p*CMB) and mercuric acetate greatly inhibit activity (Grill et al., 1995). The comparison of F-6-PPK electrophoretic mobility revealed three different bands of which one is present only in human species while the others are in animals (Scardovi et al., 1971a). Considering that such an enzyme is so useful for identification of *Bifidobacterium* at the genus level, it may be interesting to develop a specific probe based on the nucleotide sequence of such an enzyme.

The F-6-PPK Procedure

Reagents:

- 1) 0.05 M phosphate buffer (pH 6.5) containing cysteine (500 mg/liter)
- 2) NaF (6 mg/ml) and potassium (or sodium) iodoacetate (10 mg/ml)
- 3) Fructose-6-phosphate (sodium salt; 70% purity; 80 mg/ml of water)
- 4) Hydroxylamine-HCl (13.9 g/100 ml) freshly neutralized (to pH 6.5) with NaOH
- 5) Trichloroacetic acid (TCA; 15% [w/v]) solution in water
- 6) 4 M HCl
- 7) $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ (5% [w/v] in 0.1 M HCl)

Cells harvested from 100 ml of TPY liquid medium are washed twice with reagent 1 and resuspended in the same buffer (1 g of cells/ml of buffer). The cells are disrupted by sonication in the cold. Reagents 2 (0.25 ml) and 3 (0.25 ml) are added to 1.0 ml of cellular extract. After a 30-min incubation at 37°C, the reaction is stopped with 1.5 ml of reagent 4. After 10 min at room temperature, 1.0 ml each of reagents 5 and 6 are added. The mixture may be stored at room temperature prior to the addition of 1.0 ml of the color-developing reagent 7. The tubes are mixed by inversion. Any reddish-violet color (absorption

maximum 505 nm) that develops immediately is taken as a positive result. A tube without fructose-6-phosphate can serve as a blank for visual comparison (Pechère and Capony, 1968). The color is more visually evident after standing to allow debris and protein to settle. The formation of acetyl phosphate from fructose-6-phosphate is detected by the reddish-violet color of the ferric chelate of its hydroxamate (Lipmann and Tuttle, 1945).

Warning: Avoid heating during sonication, as the enzyme is heat sensitive.

In the bifidus pathway (Fig. 3) from tetrose-phosphate and hexose phosphate, through the subsequent action of transaldolase and transketolase, pentose phosphates are formed and then split in acetic and lactic acids. The latter are produced in the theoretical ratio of 1.0 : 1.5. However, the balance of the reaction can be altered by the phosphoroclastic cleavage of pyruvate into formic and acetic acids and by the reduction of acetate into ethanol (De Vries and Stouthamer, 1968; Lauer and Kandler, 1976).

Gas Chromatography Analysis Extraction of Volatile Acids. The extraction is performed in ether. To 1 ml of culture the following are added in succession: 0.2 ml of 50% H_2SO_4 , 0.4 g of NaCl and 1 ml of ethylether. After agitation and centrifugation, the ether is collected and a pinch of 4–20 mesh anhydrous CaCl_2 is added to remove traces of water.

Extraction of Nonvolatile Acids. The extraction is performed in chloroform. To 1 ml of culture, 2 ml of methanol and 0.4 ml of 50% H_2SO_4 are added in succession. After incubation at 60°C for 30 min, 1 ml of H_2O and 0.5 ml of chloroform are added. Following agitation and centrifugation, chloroform is collected at the bottom of the test tube.

The Chromatographic Analysis. The sample (10 μl) is injected. The analysis is performed as previously described (Holdeman et al., 1977).

Rapid and preliminary identification of *Bifidobacterium* isolated from dairy products may be made using α -galactosidase as a marker, inasmuch as this enzyme is not detected in *Lactobacillus* strains (Chevalier et al., 1990). This enzymatic test is included in the APY-ZYM system (bioMerieux, Marcy L'Etoile, France). Identification must be confirmed by other more reliable methods, such as the F-6-PPK test.

Species Identification This is based on morphological features, fermentation testing, the electrophoretic patterns of enzymes and other cell proteins, and determination of cell wall structures.

Morphological Features. Generally, cells of the genus *Bifidobacterium* have a rod-shaped form and can be characterized as Gram-positive, non-motile and nonsporeforming anaerobes. The

rods (2–5 μm) often bulge at one end, in the form of a cudgel or spatula, and sometimes branch. The Y- and V-forms are frequent, but more regular and coccoid forms can also be observed, depending upon the species to which the cells belong. Some species possess a characteristic cell shape that can help in the identification of the species itself. However, different cellular forms can be found within a given species, depending on the culture conditions. Tissier already noted that his bacteria took on bulge forms in response to acidity, extreme temperatures or inappropriate nitrogen sources in the substrate (Tissier, 1899). The deficit of certain factors involved in the synthesis of the cellular wall results in an increase of branches. Among these factors, there are aminosugars such as *N*-acetyl-glucosamine (Glick et al., 1960) and aminoacids such as alanine, aspartic acid, glutaminic acid and serine (Husain et al., 1972). The concentrations of sodium salts and calcium ions also influence the formation of branches (Kojima et al., 1968; Kojima et al., 1970). Therefore, pleomorphism seems to be affected by a defective synthesis of the cell wall, rather than degenerative processes, as previously suggested. Biavati et al. (1992a) observed the phenomenon called “phase variation” (Trüper and Krämer, 1981) in *B. animalis*. The transition of colony phenotype accompanied by a dramatic change in cell morphology was described. The cells forming transparent (T) colonies, which were minute and mostly spherical, were seen to transition into cells forming opaque (O) colonies, which had species-specific shapes and dimensions (Fig. 11).

Fermentation Tests. One of the early identification schemes of the species of *Bifidobacterium* genus was based on a simple carbohydrate fermentation pattern (Mitsuoka, 1969). This method is still in use, but data obtained from fermentation tests cannot be considered final but need to be confirmed as by DNA-DNA hybridization or electrophoresis of cellular proteins. The simple carbohydrate fermentation characteristics of species of *Bifidobacterium* are reported in Table 5. Encouraging data were obtained from studies of the fermentation of complex polysaccharides and of mucin (Tables 6a and b). The largest number of species could ferment D-galactosamine, D-glucosamine, amylose and amylopectin. Many of the species isolated from animal habitats showed reduced fermentation activity. Some species of human origin selectively ferment certain components, and this allows the development of a key for the differentiation of human *Bifidobacterium* species (Fig. 4). *Bifidobacterium bifidum* was the only species to ferment porcine gastric mucin, *B. infantis* was the only species to ferment D-glucuronic acid; strains of *B. longum* fermented

Fig. 11. Colonies on trypticase-phytone-yeast extract (TPY) stabs: (1) strain P 23 (ATCC 27536), (2) T and O, and (3) T colonies with O papillae; and cells from (4) O and (5) T colonies and from (6) the mixed type colonies.

arabinogalactan and the gums arabic, ghatti and tragacanth; α -L-fucose was fermented by strains of *B. breve*, *B. infantis* and *B. pseudocatenulatum*; strains of *B. dentium* fermented guar gum and locust bean (Crociani et al., 1994). Only *B. inopinatum* and *B. denticolens* strains fermented dextran (Crociani et al., 1996b).

Fermentation Test Procedures and Carbohydrates Conventionally Used. For the tests of carbohydrate fermentation, the modified TPY basal medium with half quantities of Trypticase, Phytone and Yeast extract without glucose (TPYM, pH 7.5) is used. As a pH indicator, bromocresol purple is added (30 mg/liter). About 9 ml of TPYM is dispensed into tubes that are then sterilized at 110°C for 30 min. Solutions (5%) of the substrates to be tested are sterilized by Tyndallization (except for arabinose and xylose which are sterilized by filtration) and added (1 ml) to the tubes containing the TPYM. Thus a final con-

centration of each carbohydrate is 0.5%. The following carbohydrates are tested and routinely used to characterize the species: arabinose, cellobiose, dextrin, fructose, galactose, glycerol, gluconate, inulin, lactate, lactose, maltose, mannitol, mannose, melibiose, raffinose, rhamnose, ribose, saccharose, salicin, sorbitol, starch, trehalose and xylose. Glucose is included as a positive test control. The cell suspension used to inoculate the assay media is from 10 ml-TPYM cultures containing 0.15% glucose. The cells from these cultures are centrifuged and resuspended in 5 ml of TPYM. Three drops of cell suspension are added to each assay tube. Strain positivity is determined from growth, color changes and pH measurements (at least one unit of pH decrease in respect to test without glucose is considered for strain positivity) after 5–7 days of incubation at 37°C in anaerobiosis. Strains fermenting gluconate produce CO₂ from this compound and less acid than that produced

Symbols: +, 90% or more of strains are positive; -, 90% or more of strains are negative; v, 11–89% of strains are positive; and nd, not determined.

^aAll the strains tested ferment glucose, but do not ferment glycerol, lactate and rhamnose.

^bA few strains do not ferment this sugar.

^cWhen positive, it is fermented slowly.

^dSome strains ferment this sugar.

^eSome strains are negative, especially from rat and rabbit feces.

^fSome strains can ferment it weakly.

^gGenerally delayed or slight fermentation.

^hSome strains from sewage ferment this sugar.

ⁱSome strains are weak fermenters.

^jReported as “sometimes not fermented” (Matteuzzi et al., 1971).

^kSugars indicated “v” give mostly erratic results.

¹A few strains do not ferment pentoses.

Data for *B. gallicum* is from Lauer (1990); for *B. lactis* from Meile et al. (1997); for *B. thermacidophilum* from Dong et al. (2000); and for *B. gallinarum* from Watabe et al. (1983).

from glucose or other sugars, and cells are generally very minute (Sgorbati et al., 1970); the indicator turns yellow more slowly and acid development should be carefully compared with that obtained in the absence of added sugars.

Complex Carbohydrates, Polyalcohols, Mucins and Gums. The fermentative tests are carried out with some variations. The compounds which can be used are *N*-acetyl-glucosamine, alginate, D-amygdalin, amylopectin, amylose,

Symbols: +, 90% or more of strains are positive; —, 90% or more of strains are negative; v, 11–89% of strains are positive; and nt, not tested.

^aA few strains ferment this sugar.

^bA few strains do not ferment this sugar. Substrates not fermented: alginate, bovine submaxillary mucin, chondroitin sulfate, dextran, α -D-fucose, α -L-fucose, D-galacturonate, D-glucuronate, heparin, hyaluronate, laminarin, ovomucoid, polygalacturonate, porcine gastric mucin, gums: arabic, ghatti and karaya.

arabinogalactan, bovine submaxillary mucin, chondroitin sulfate A, dextran, heparin, alpha-D-fucose, alpha-L-fucose, D-galactosamine, D-galacturonate, D-glucosamine, D-glucuronate, gum arabic, gum ghatti, gum guar, gum karaya, gum locust bean, gum tragacanth, hyaluronate, laminarin, ovomucoid, pectin, polygalacturonate, porcine gastric mucin, and xylan. They were all purchased from Sigma Chemical Co. (St. Louis, MO). Glucose is added to one assay tube as a positive control to check growth under the assay conditions. Basal medium TPYM (adjusted to pH 7.5) is used throughout the procedure and dispensed (2 ml) into test tubes, which are autoclaved twice at 100°C separated by a 24-h interval. Substrates are added up to a final concentration of 0.5% (and 1% for bovine submaxillary mucin, porcine gastric mucin and ovomucoid). D-Galactosamine, D-glucosamine, heparin, ovomucoid and pectin are added to autoclaved medium as filter-sterilized solutions because the pH of these solutions in the basal medium varies markedly when autoclaved; the pHs of the other autoclaved substrates are 7.2–7.5. Inoculum (0.025 ml) consists of cells derived from 10 ml of TPYM (containing 0.15% glucose), harvested by centrifugation and resuspended in 5 ml of TPYM to avoid introduction of glucose into the test medium. Bromocresol purple (30 mg/ml) is added to the test medium as an indicator. Strain positivity is determined from growth, color changes and pH measurements (at least one unit of pH decrease in respect to test without glucose is considered for strain positivity) after 5–7 days of incubation at 37°C in anaerobic jars.

Electrophoretic Pattern of Enzymes As shown in Table 3, 6-phosphogluconate dehydrogenase (6-PGD) and transaldolase isozymes should be used as additional characters to distinguish bifidobacterial species. The electrophoretic pattern of 6-PGD and transaldolase of some selected species is shown in Fig. 12.

Fourteen isozymes of transaldolase and 19 of 6-PGD, isolated from 1,206 strains of 24 bifidobacterial species, were identified and numbered (Table 2). Sixty percent of the strains were identifiable on the basis of these isozymes (Scardovi et al., 1979a). Antisera against eight purified transaldolases further established natural relationships among the species (Sgorbati, 1979a; Sgorbati and London, 1982a; Sgorbati and Scardovi, 1979b). The horizontal starch-gel electrophoresis system of Smithies (1955) is the preferred method for enzyme detection.

The Electrophoresis Procedure for Enzyme Detection Transaldolase. TRIS (hydroxymethyl) aminomethane (TRIS; 16.3 g/liter) and citric acid monohydrate (9.0 g/liter) are used as bridge

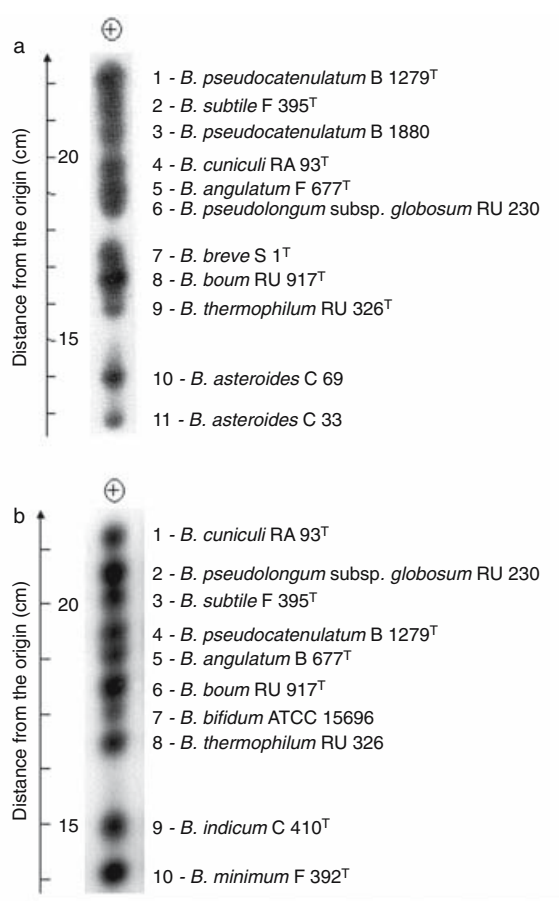

Fig. 12. Coelectrophoretic run of pooled cell-free extracts from 11 (a) and 10 (b) *Bifidobacterium* reference strains after staining for 6-phosphogluconate dehydrogenase (a) and transaldolase (b).

buffer (pH 7.0; dilute this 1:15 for use as gel buffer). Hydrolyzed starch (90 g; Sigma, cat. number S-4501) is added per liter of buffer. The mixture is agitated while boiling for 5 min, and gas is removed under reduced pressure. The liquid is poured into a plastic three-frame mold (the dimensions 12.0 × 37.0 × 0.9 cm are suitable to accommodate 12 samples at a time).

Samples (5–10 µl on 0.5 × 0.5 cm Whatman 3-mm paper cuts) of bacterial extracts (cells suspended in 0.05 M phosphate buffer, pH 7.0, sonicated and centrifuged) are generally run for 15–20 h with a current of 15–20 mA. The middle slab is preferably used for staining by a flooding technique. The developing solution contains (per 100 ml of distilled water): fructose-6-phosphate (Na salt, 98% purity, Sigma), 400 mg; sodium arsenate, 370 mg; glycine, 240 mg; NAD, 13 mg; D-erythrose-4-phosphate (60–75% purity, Sigma), 16 mg; phenazine methosulfate, 2 mg; nitroblue tetrazolium (NBT, Sigma), 20 mg; and glyceraldehyde-3-phosphate dehydrogenase, about 130–150 IU.

6-Phosphogluconate Dehydrogenase (6-PGD). Use trisodium citrate·2H₂O (120 g/liter; adjusted to pH 7.0 with citric acid) as a bridge buffer and histidine (0.75 g/liter) plus NaCl (1.5 g/liter; pH 7.0) as a gel buffer. Prepare the gel in the same way as the gel used for detecting transaldolase was prepared. The developing solution is made as follows: 0.5 M TRIS-HCl buffer (pH 7.0), 10 ml; 6-phosphogluconate (trisodium salt, Sigma), 250 mg; NADP, 20 mg; NBT, 20 mg; phenazine methosulfate, 2 mg; and distilled water, 90 ml.

Electrophoretic Patterns of Cellular Proteins The electrophoretic patterns of cellular proteins were used to confirm the taxonomic identification of 1,094 bifidobacterial strains belonging to the known species of the genus: excellent correlation was found between data obtained by electrophoresis and by DNA-DNA hybridization. In addition, a sort of "genus band" is clearly visible in all gel electrophoresis patterns; this band migrates to the same position for all strains, with the exception of *B. boum*, where it is somewhat less anodic. The presence of this "genus band" is a good indication that an unknown organism belongs to the *Bifidobacterium* genus (Biavati et al., 1982). Within species, strains that have 80% or greater DNA homology have identical or nearly identical profiles. *Bifidobacterium animalis* is the only exception: in such species, the PAGE pattern of strains isolated from rats appears to differ from that of strains isolated from sewage, rabbits and chickens (Biavati et al., 1982). The intestinal origin of strains isolated from sewage and fermented milk products was determined by comparing electrophoretograms of cellular soluble proteins (Mattarelli et al., 1992). This procedure was confirmed as one of the most useful in rapidly identifying unknown bifidobacterial isolates. Provided that highly standardized conditions are used throughout the procedure of cultivation and electrophoresis, computer-assisted numerical comparisons of protein patterns are feasible, and a database can be created for identification purposes. This allows large numbers of strains to be compared and grouped in clusters of closely related homology.

The Electrophoresis Procedure for Detecting Cellular Proteins Stock solution of the resolving gel contained 24.4 g of acrylamide, 0.64 g of bis-acrylamide and 250 ml of 0.4 M TRIS-HCl, pH 8.8. After filtration the solution is stored in the dark at 4°C. For each gel (16 × 20 cm vertical gels, 1.5-mm thick) 45 ml of stock solution is drawn into a 50-ml syringe. About 16 µl of TEMED and 0.35 ml of freshly prepared aqueous 10% ammonium persulfate are injected through the tip of

the 50-ml syringe. An 18-gauge needle is affixed and the gels are cast in previously assembled plates. Stock solution for the stacking gel contains 3.46 g of acrylamide, 0.09 g of bis-acrylamide and 70 ml of 0.2 M TRIS-HCl, pH 7. After filtration, this solution is stored in the dark at 4°C. At the moment of the use, 10 µl of TEMED and 0.4 ml of tracking dye (0.25% bromophenol blue in water [w/v]) are added to 10 ml of solution and the mix is drawn into a 50-ml syringe. Freshly prepared aqueous 10% ammonium persulfate (0.25 ml) is added, and the solution is injected over the resolving gel while a 20-tooth comb is inserted. Samples are prepared from 10 ml of TPY cultures. Bacterial cells are harvested by centrifugation and washed once in 0.2 M TRIS-HCl, pH 7. Cells suspended in 0.15 ml of the same buffer in a tube containing approximately 0.15 g of 75–110 µm diameter glass beads are disrupted using a mechanical agitator (for total of 30 min, applying 2-min periods of agitation separated by 1-min periods of rest). Cell walls and residual cells are harvested by centrifugation. About 20 mg of saccharose was added to the supernatant to increase its density; 35 µl of samples are layered under the buffer solution for each well. Electrophoresis is run at 15°C at constant voltage of 200 V and about 33 mA initial current. The running buffer contains 3 g of TRIS-HCl and 15 g of glycine per liter. Electrophoresis is stopped when the tracking dye reaches the bottom of the gel. The gel is placed in 12% trichloroacetic acid for 30 min before staining. The trichloroacetic acid solution is replaced with Coomassie blue solution (2 g of Coomassie Brilliant blue, 450 ml of methanol, 200 ml of acetic acid, and 800 ml of H₂O) for 30 min. The gel is destained with 25% ethanol plus 8% acetic acid (v/v) for about 12 h. After 1 or 2 h at room temperature, the depth of the color is adjusted by adding fresh destaining solution. The gels are then photographed and kept in small plastic bags, after the destaining solution is discarded.

Cell Wall Structure The most extensive study of murein (peptidoglycan) types in bifidobacteria cell walls has been conducted by Kandler and Lauer (1974) and Lauer and Kandler (1983). A considerable variety of murein types was found in the genus *Bifidobacterium*, and many species are clearly distinguishable on this basis. The same authors report that bifidobacteria cell walls contain significant amounts of polysaccharides, which usually consist of glucose and galactose often accompanied by rhamnose. The structure and composition of the cell wall polysaccharides have also been investigated (Habu et al., 1987; Nagaoka et al., 1988). Traces of lipoteichoic acid associated with the fraction of the cell wall that remains insoluble after lysozyme treatment were

found in *Bifidobacterium bifidum* (Veerkamp et al., 1983). Its chemical composition and structure have been studied (Fischer et al., 1987; Op Den Camp et al., 1984). Immunochemical studies indicated that lipoteichoic acid is a common antigen within the genus *Bifidobacterium* (Op Den Camp et al., 1985b). Furthermore, proteins and lipoteichoic acid are responsible, either independently or in dynamic complexes, for the hydrophobic character of the bifidobacterial surface (Op Den Camp et al., 1985a).

Mukai et al. (1997) suggest that the cell surface proteinaceous components are involved in the adhesion of *B. adolescentis*. The study of cellular structures (proteins, lipoteichoic acids, etc.) as well as the interaction of cells with substrate (in vivo and in vitro adhesion) is particularly important for understanding the mechanisms that regulate bacterial adhesion and therefore colonization. Protein ligands present on the cell surfaces and/or in the culture medium have been identified by Bernet et al. (1993) in some strains of bifidobacteria of human origin (*B. breve*, *B. longum*, *B. bifidum* and *B. infantis*). These studies have shown that different strains belonging to the same species adhere differently to intestinal cells of the Caco-2 and HT29MTX lines. More recently Pérez et al. (1998) have studied the adhesive capacity of some strains of human origin, showing that in many cases adhesion was linked to the self-agglutination capacity of such strains: strains with a good self-agglutination capacity tested positive by hemagglutination and showed a high surface hydrophobicity.

The study of the cell wall-associated proteins in *B. pseudolongum* subsp. *globosum* is part of a study of the plasmid functions of bifidobacteria: nearly 40% of 150 strains of different animal origin were shown to have 3–8 cell wall-associated proteins whose distribution was ascertained with PAGE and with immunoblotting techniques (Mattarelli et al., 1993). Using plasmid-free clones obtained by “curing,” the involvement of certain plasmids in determining the surface protein patterns was ascertained. Sensitivity to the lytic and bactericidal activities of lysozyme and cationic polypeptides was found to be related to the presence of a plasmid-dependent surface protein of high molecular weight (Mattarelli et al., 1997). The effect of the growth temperature on the biosynthesis of cell wall proteins has been studied in 70 strains of *B. pseudolongum* subsp. *globosum*. The production of cell-wall proteins is temperature-dependent. There is a positive correlation between the increase in growth temperature and the expression of the majority of bifidobacterial outer proteins (BIFOPs), which appears to be a common feature of *B. pseudolongum* subsp. *globosum* species and present in all the strains tested. Fur-

thermore, at high-growth temperatures, the presence of a new common protein, which could be regarded as a temperature inducible protein, was detected in all the strains studied. The relationship of BIFOP, growth temperature and hydrophobicity has been investigated for some strains. At medium-growth temperatures, the cell hydrophobicity was strictly correlated with the BIFOP expression, whereas at low- and high-growth temperature, the presence of BIFOP only partially influenced the hydrophobic features (Mattarelli et al., 1999c).

A deeper understanding of the ecological variability of the surface structure in bifidobacteria and their functions in the multifaceted relationships of host and bacterium is thought to be a prerequisite for a less empirical use of the bifidobacteria in foods and pharmaceutical preparations for humans and animals.

GENOTYPIC IDENTIFICATION PHYLOGENETIC APPROACH. The two main tools used for comparative phylogenetic analysis of *Bifidobacterium* are described below.

Rec A Analysis. A fragment of the Rec A gene, which is usually present in bacteria and highly conserved, is amplified by polymerase chain reaction (PCR) and sequenced. The phylogenetic relationship obtained correlates well with the analysis of the complete rRNA gene and, given its speed and ease, is a valuable tool for comparative phylogenetic analysis of human intestinal isolates. This concept was applied to the genus *Bifidobacterium* by Kullen et al. (1997).

Sequence Analysis Using 16S rRNA. Using primers directed at universally conserved regions at both ends of the gene, the 16S rRNA directly from colonies is PCR-amplified. The amplicon (1.5 kb) is then sequenced and compared to the rRNA database. This allows an accurate typing of unknown isolates and determination of their phylogenetic position. This technique has greatly helped the understanding of phylogenetic relationships among the major microbial genera in the human intestine. Leblond-Bourget et al. (1996) comparing 16S rRNAs concluded that the evolutionary distances exhibited by most bifidobacteria are such that these organisms belong to the same genus. The 16S rRNA analysis was useful in discriminating between genera and confirmed the separation between genus *Gardnerella* and *Bifidobacterium*. Despite considerable phenotypic diversity, all of the bifidobacteria whose sequences have been determined are closely related (levels of 16S rRNA similarity >93%). Furthermore Miyake et al. (1998) showed that, based on a 16S rRNA analysis, 21 *Bifidobacterium* species belonged to a cluster phylogeneti-

cally distinct from the other genera; *Gardnerella vaginalis* ATCC 14018 is included in this cluster. The cluster was divided into two subclusters: subcluster 1 composed of most species of *Bifidobacterium* and *G. vaginalis* and subcluster 2 consisting of two species, *B. denticolens* and *B. inopinatum*. Langendijk et al. (1995) have developed 16S rRNA gene probes specific for the genus *Bifidobacterium* which enable the exclusive detection of bifidobacteria in fecal samples through in situ hybridization.

SPECIES IDENTIFICATION CLASSICAL TECHNIQUES. These include determination of G+C content and DNA-DNA homology.

Percent G+C Content The DNA of bifidobacteria has quite a high content of guanine and cytosine (G+C; Table 2). The G+C value varies from 55–67 mol%, with differences among species (Scardovi, 1986). The only exception, *B. inopinatum* (one of the three species found in dental caries), has a G+C content of 45% (Croci et al., 1996b).

The Procedure for Determining G+C Content DNA base composition was calculated from melting temperatures determined with a response series UV-visible spectrophotometer equipped with a Response II thermal programmer. *Escherichia coli* K-12 DNA was used as a standard. The mol% of G+C is calculated by the formula of Marmur and Doty (1962).

DNA-DNA Homology DNA-DNA homology is the gold standard method to establish relationships within and between the species. A species is defined as an entity which includes "... strains with approximately 70% or greater DNA-DNA relatedness and with 5°C or less δT_m ." (Wayne et al., 1987). Both values must be considered and phenotypic characteristics must be similar in every species. DNA-DNA homology is not widely applied because it is time-consuming and laborious even if it is still the most reliable method for species identification.

Procedure for Determining DNA-DNA Homology The percentage of homology between DNAs is assessed through the direct-binding membrane method (Johnson, 1981). The DNA is from cells grown in 1 liter of TPY medium. Cells harvested by centrifugation are washed twice in saline-EDTA buffer (0.15 M NaCl and 0.1 M EDTA, pH 8.0) and suspended in 40 ml of saline-EDTA; lysozyme is then added up to a final concentration of 3 mg/ml. Subsequently, DNA is extracted using the Marmur (1961) technique. The reference DNA, diluted in 0.1 X SSC (1 X SSC: NaCl 0.15M, trisodium citrate 0.015 M, pH 7) at a concentration of

50 µg/ml, is denatured with NaOH (final concentration 0.25 M) for 15 min at 60°C, then cooled and quickly brought to pH 7 with HCl. The solution is diluted 1:10 with cool 6X SSC, then slowly filtered twice at low temperature through a 15-cm nitrocellulose membrane (Sartorius Membrane filter SM 11306) presoaked in 6X SSC. The filter is dried in air for a few minutes, then in the oven at 80°C for two hours. The filter is cut with a paper punch into small filters 10.5 mm in diameter and then stored at 4°C. The amount of DNA fixed is about 25 µg/cm². The labeled DNA is obtained by nick translation using [³H]-dCTP (Amersham-Pharmacia-Biotech, cat. number TRK 625-9.25 MBq) following the protocol of the Nick Translation Kit (Amersham-Pharmacia-Biotech, cat. number N 5000). This DNA is sheared by passage through a syringe needle 3–4 times and denatured by heating in a boiled water bath for 10 min prior to use. Hybridization consists in the comparison between the labeled DNA with the DNA fixed on the filters. The filters with immobilized DNA (reference DNA) are preincubated at 60°C in 0.8 ml of the pre-incubation mixture (2X SSC with 0.02% bovine serum albumin, 0.02% polyvinylpyrrolidone, 0.02% Ficoll 400) for 1 h at 60°C. The filters are removed and the excess water blotted off. The filters were then placed individually in 4-ml screw-cap vials containing 0.15 ml of sterile H₂O, 0.04 ml of 11.1X SSC, and 10 µl of labeled DNA. The vials were gently shaken with a wrist-action shaker for 12 h at 69°C, 25°C below the melting temperature (T_m) as determined in 1X SSC. After incubation, the filters are washed twice with 0.8 ml of 2X SSC at 69°C, dried under an infrared lamp, and counted with a liquid-scintillation counter. Homology values were calculated in percent of binding with respect to 100% homology of the reference strain.

Recently Described Molecular Techniques

These include internal transcribed spacer (ITS) sequence analysis; colony hybridization with nucleic acid probe techniques; pulse-field gel electrophoresis (PFGE); ribotyping; restriction fragment length polymorphism (RFLP) of the 16S rRNA gene; amplified ribosomal DNA restriction analysis (ARDRA); random amplified polymorphic DNA (RAPD), or arbitrary primed-PCR (AP-PCR); fluorescent in situ hybridization (FISH); and *ldh* gene sequence comparison.

Internal Transcribed Spacer Sequence Analysis. The analysis of the internal transcribed spacer, a region of DNA between the 16S and 23S rRNA gene universally present in bacteria, has been used to complement other rRNA sequence analysis. This molecule exhibits very

low sequence conservation and for this reason cannot be used as an accurate phylogenetic marker. In addition, the ITS regions within the same bacterial strains can be heterogeneous. However, this analysis is feasible because PCR can be used to amplify the entire molecule from colonies. The ITS has been used for a more detailed analysis of bifidobacteria. The work by Leblond-Bourget et al. (1996) showed that 16S rRNA and ITS analysis are useful tools to dissect the bifidobacteria taxonomy. The ITS analysis was able to discriminate intra- and inter-specific differences that were in good correlation with 16S rRNA data. Furthermore the ITS approach allowed the authors to propose *B. infantis*, *B. suis* and *B. longum* as belonging to the same species.

Colony Hybridization with Nucleic Acid Probes. Colonies can be directly examined for the presence of a specific DNA sequence recognized by a labeled probe. Short probes (20 bases) can be directed to rRNA regions known to be genus- or species-specific. In the study of bifidobacteria, this approach has been used to obtain species-specific probes (Ito et al., 1992; Mangin et al., 1995; Yamamoto et al., 1992) and genus-specific probes (Kaufmann et al., 1997; Langendijk et al., 1995).

Pulsed-Field Gel Electrophoresis. The PFGE method allows very large fragments of DNA to migrate through an agarose gel under a pulsed electric field. Genomic DNA is digested with a rare restriction enzyme. The unique pattern of DNA fragment distribution in the gel is the fingerprint of the strain. Owing to the large size of the DNA fragments, all the technical operations need to be carried out on cells embedded in an agarose gel (inserts). It is perhaps the most discriminatory technique at the strain level, even if it has no value in taxonomic identification. Bifidobacteria strains of different species were characterized by PFGE by different authors (Bourget et al., 1993; Roy et al., 1996; O'Riordan and Fitzgerald, 1997). The usefulness of this technique has been demonstrated by McCartney et al. (1996) and Kimura et al. (1997), who analyzed *Bifidobacterium* and *Lactobacillus* populations in fecal samples obtained from human subjects in a one-year period. It was demonstrated that each subject harbored numerically predominant strains that were characteristic of the particular human host.

Ribotyping. The total DNA is isolated and completely digested with a frequently cutting restriction enzyme. The restricted fragments are then separated by agarose gel electrophoresis and hybridized with a probe specific for the 16S (most commonly used), 23S or 5S rRNA genes. The visualized pattern represents a characteristic fingerprint. The method is well suited for the

analysis of bacteria possessing multiple copies of rRNA genes in their genome, but it is not useful for those bacteria possessing only a single copy of rRNA genes. This technique is very reproducible. Its effectiveness has been demonstrated for the analysis of human intestinal bifidobacteria (Kimura et al., 1997; McCartney et al., 1996). This fingerprinting technique is limited by the fact that it is not as discriminative as PFGE, requires culturing of bacteria, and is labor intensive.

Restriction Fragment Length Polymorphism of the 16S rRNA Gene. The gene for 16S rRNA is amplified by PCR with primers recognizing universally conserved regions in the gene. The amplicon is then restricted and the resulting fragments are analyzed by electrophoresis, giving a characteristic pattern of distribution. Kullen et al. (1997) used this technique to differentiate an ingested bifidobacteria from the indigenous bifidobacteria in human subjects. Kok et al. (1996) developed three 16S rRNA-targeted primers specific to probiotic strain LW 420, probably *B. animalis*, to monitor the presence of this strain in the human intestine. As this is a PCR-based technique, it can be carried out on very few cells without culturing.

Amplified Ribosomal DNA Restriction Analysis. ARDRA is a potent and discriminating tool for organisms at the species level. In this technique, the DNA sequence of a 16S rRNA region is amplified by PCR using genus-specific primers, then the products of amplification are digested with restriction enzymes, and the pattern fragment obtained is used to distinguish different species. Roy and Sirois (2000), by utilizing this technique, are able to discriminate among *B. infantis*, *B. longum* and *B. animalis*.

Random Amplified Polymorphic DNA or Arbitrary Primed-PCR. A PCR-based technique, RAPD or AP-PCR uses only a single start primer (10–12 bases) with an arbitrarily chosen sequence. Usually the stringency of the reaction is reduced, allowing the primer to bind to regions where it exhibits greatest homology. The amplified products are separated by agarose gel electrophoresis. The pattern obtained from different samples can be compared. This is a rapid technique, very discriminative and can be applied to organisms for which no sequence information is available; however, it is not very reproducible because a subtle change in reaction conditions can dramatically change the binding patterns (Williams et al., 1990; Welsh and McClelland, 1990). In addition, RAPD analysis has been applied to the characterization of genetic variability of bifidobacteria isolated from rats fed particular diets (Fanedl et al., 1998). In this study, results indicated the presence of a large degree of genetic variability among bifidobacteria in the

rat gut and demonstrated the usefulness of RAPD analysis for the study of microbial diversity in complex ecosystems. Vincent et al. (1998), using five primers, distinguished three different species of *Bifidobacterium* (*B. breve*, *B. bifidum* and *B. adolescentis*) based on similarity of the RAPD profiles to known reference strains. This technique is also useful for placement of industrial strains into specific clusters (either *B. longum/infantis* or *B. animalis/lactis*).

Fluorescent In Situ Hybridization. Oligonucleotide probes labeled with fluorescent molecules are allowed to hybridize directly onto cells fixed on glass slides. Subsequently the probes can be visualized using fluorescence microscopy. The technique can be applied to the determination of specific mRNA within cells. Langendijk et al. (1995) and Harmsen et al. (Harmsen et al., 1999; Harmsen et al., 2000) utilized this technique to detect bifidobacteria in fecal samples, providing quantitative data on gut flora.

ldh Gene Sequence Comparison. Roy and Sirois (2000) utilized *ldh* gene sequence comparison to distinguish between *B. longum* and *B. infantis* and between *B. animalis* and *B. lactis*. This technique permits differentiation of *B. longum* from *B. infantis*, but not *B. animalis* from *B. lactis*. Owing to the low number of species tested, the validity of this method is difficult to judge.

Preservation

SHORT-TERM METHODS A chopped meat medium (Holdeman et al., 1977) is probably the best one for preservation of strains of bifidobacteria in liquid media. To avoid dehydration and diffusion of O₂, sterilized chopped meat (pre-reduced anaerobically) in tubes sealed with butyl stoppers (Holdeman et al., 1977) is inoculated, and after growth, the cultures can be stored at room temperature or at 5°C for several months.

LONG-TERM METHODS Longer maintenance can be achieved both by freezing below 130°C (deep freezer) or in liquid nitrogen and by freeze-drying. The following cryoprotective agents may be used: skim milk solution (skim milk 10%, lactose 3%, yeast extract 0.3%; the solution after shaking for 20 min is autoclaved at 110°C for 30 min) or saccharose solution (saccharose 12%, yeast extract 0.3%, peptone 0.5%; the solution is autoclaved at 110°C for 30 min). Both cryoprotective agents allow for sufficient survival of the strains in the survival process: the level of survival is a characteristic linked to strains rather than species (B. Biavati and P. Mattarelli, unpublished data). In our experience lyophilized cultures kept at room temperature remain alive after 30 years. For details and other methods, see Ghera (1994).

Physiology

SENSITIVITY TO OXYGEN Bifidobacteria are anaerobic microorganisms. However, the sensitivity to oxygen changes according to the species and the different strains of each species. The mechanisms which are at the basis of their tolerance to oxygen are controversial (De Vries and Stouthamer, 1968). The reasons why bifidobacteria are anaerobic may vary: some require a high redox potential or enzymes that are sensitive to H₂O₂. Phosphoketolase is indeed sensitive to H₂O₂, but direct toxicity of O₂ has not yet been demonstrated. Bifidobacteria are all catalase-negative, yet among the species tolerant to air, *B. indicum* and *B. asteroides* become catalase-positive if they are grown in the presence of air, respectively with or without addition of hemin (Scardovi and Trovatielli, 1969a). Some strains of *B. bifidum* seem to be able to synthesize at a low extent some catalase when exposed to air (Bezkorovainy, 1989).

OPTIMUM TEMPERATURE Optimum temperature for growth is 37–41°C, whereas no growth occurs below 20°C and above 46°C with the exception of *B. thermacidophilum*, which is able to grow at 49.5°C (Dong et al., 2000). Some changes occur depending upon the habitat of origin. Growth at 45°C seems to discriminate between animal and human strains, since most of the animal but not the human strains are able to grow at this temperature (Gavini et al., 1991).

OPTIMUM pH The optimum pH at the beginning of the growth is between 6.5 and 7.0. No growth is recorded at pH lower than 4.5 or higher than 8.5 with the exception of *B. thermacidophilum*, which is able to grow at pH 4.0 (Dong et al., 2000). Bifidobacteria are acid-tolerant but are not acidophilic microorganisms.

HEXOSE METABOLISM Hexose metabolism in bifidobacteria occurs through a characteristic sequence called the “fructose-6-phosphate shunt” or “bifidus shunt” (Scardovi and Trovatielli, 1965; De Vries et al., 1967; Fig. 3). The key enzyme of this pathway is fructose-6-phosphate-phosphoketolase (EC 4.1.2.22), which cleaves hexose phosphate to erythrose-4-phosphate and acetyl-phosphate. Pentose phosphates are formed from tetrose phosphate and hexose phosphate, through the subsequent action of transaldolase and transketolase, and then split into acetic and lactic acids. The latter are produced in the theoretical ratio of 1.0:1.5. However, the balance of the reaction can be altered by the phosphoroclastic cleavage of pyruvate into formic and acetic acids and by the reduction of acetate

into ethanol (De Vries and Stouthamer, 1968; Lauer and Kandler, 1976). During the metabolism of hexose, there is no production of carbon dioxide, except in the degradation of gluconate. Different bifidobacterial species produce different amounts of acetate, lactate, ethanol and formate under the same conditions. Furthermore, variations of growth conditions, such as quality and quantity of the carbon source, may result in the production of varying amounts of fermentation products.

Occasionally, claims are made that other pathways may also exist. It has been stated that the glycolytic enzyme aldolase (EC 4.1.2.13) and the hexose monophosphate shunt enzymes glucose-6-phosphate dehydrogenase (EC 1.1.1.49) and 6-phosphogluconate dehydrogenase (EC 1.1.1.44) were absent from many human bifidobacteria but not necessarily from animal species. *Bifidobacterium asteroides* and *B. indicum* (isolated from honeybee), in fact, both have hexose monophosphate shunt enzymes, but not aldolase (Scardovi and Trovatielli, 1969a). Both aldolase and the two hexose monophosphate shunt enzymes are present in the rumen bacteria *B. pseudolongum* subsp. *globosum* and *B. thermophilum* (Scardovi et al., 1969b). *Bifidobacterium catenulatum*, *B. longum* and *B. angulatum* among the human species contain both aldolase and 6-phosphogluconate dehydrogenase. The physiological role of these enzymes in bifidobacteria is unclear.

The enzymes of the Leloir pathway of galactose metabolism, i.e., galactokinase (EC 2.7.1.6), hexose-1-phosphate uridylyltransferase (EC 2.7.7.12) and UDP galactose 4-epimerase (EC 5.1.3.2), are constitutive in glucose-grown cells of bifidobacteria, whereas in other microorganisms these enzymes are induced by galactose or fucose (Lee et al., 1980). The enzymatic carboxylation of phosphoenolpyruvate to oxaloacetate in some bifidobacteria from human feces and from honeybees has been compared to the corresponding activity in strains of *Actinomyces bovis* and *Actinomyces israelii*. In bifidobacteria, this activity is independent of the phosphate acceptor and is irreversible, whereas in *Actinomyces* it is inosine- or guanosine-diphosphate-dependent (Chiappini, 1966).

ULTRASTRUCTURE The ultrastructure of bifidobacteria has received little attention. Overman and Pine (1963) first reported electron micrographs of *B. bifidum* subsp. *pennsylvanicum*. Zani and Severi (1982) made a more extensive investigation of the ultrastructure of *B. bifidum* strain S28a of Reuter (ATCC 15696). Comparative studies of the ultrastructure of *Bifidobacterium* species comprising this genus also have been made (Novik et al., 1994; Novik, 1998).

ENZYMES *Bifidobacteria* utilize a great variety of mono- and disaccharides as carbon sources and are able to metabolize also complex carbohydrates that are normally not digested in the small intestine. This latter feature should give an ecological advantage to colonizers of the intestinal environment where complex carbohydrates, such as mucin, are present either because of production by the host epithelium or introduction through the diet. The selective stimulation of the growth of bifidobacteria by simple or complex carbohydrates is the basis of the prebiotic concept. The study of enzymes involved in the bifidobacterial carbohydrate degradation has therefore received great attention. Carbohydrates that are considered bifidogenic are: oligosaccharides (fructo-oligosaccharides, *trans*- β -D-galactosyl-oligosaccharides, α -D-galactose-oligosaccharides such as raffinose and stachyose, the latter found in legumes or beans, and endogenous carbohydrates such as mucus and glycoproteins) and polysaccharides such as inulin.

Bifidobacteria possess an array of enzymes that allow them to utilize different types of carbohydrates to adapt and compete in an environment with changing nutritional conditions; these enzymes are inducible in the presence of specific substances. Amongst these enzymes α - and β -glycosidases, neuraminidases (EC 3.2.1.18), α -glucosidases (EC 3.2.1.20) and β -D-glucosidases (EC 3.2.1.21), α -D-galactosidase (EC 3.2.1.22) and β -D-galactosidase (EC 3.2.1.23) are included. Extracellular α - and β -glycosidases that degrade intestinal mucin oligosaccharides and glycosphingolipids of the lacto-series type 1 chain were found in human fecal bifidobacteria (Falk et al., 1990). A β -glucosidase that also has β -D-fucosidase activity was found in *B. breve* (Nunoura et al., 1996). A novel β -glucosidase, which is inducible and capable of catalyzing the hydrolysis of sennosides, was purified from a strain of *Bifidobacterium* sp. (Yang et al., 1996). α -D-Galactosidase, which exhibited a high substrate specificity for α -galactoside linkages, seems to be highly specific for bifidobacteria and *Actinomyces* of human origin (Desjardins and Roy, 1990; Hartemink et al., 1996); this enzyme is a specific test in the APY identification system for bifidobacteria. Transglycosidase activity of *B. adolescentis* α -galactosidase has been recently studied to utilize new types of α -galactosides as prebiotic and synbiotic substrates (Van Laere et al., 1999). Several isoenzymes of β -galactosidase were detected among strains of bifidobacteria by means of electrophoresis (Roy et al., 1994). Interestingly in this study, the authors assess that dairy-related bifidobacteria (*B. bifidum*, *B. breve*, *B. infantis* and *B. longum*) as well as *B. animalis* could be better differentiated from

other bifidobacteria by comparison of their β -galactosidase electrophoretic patterns.

In *B. adolescentis* cells grown on transgalactosylated oligosaccharides (TOS), in addition to the lactose-degrading β -galactosidase, another β -galactosidase named " β -galactosidase II" (β -gal II) was detected, showing activity towards TOS but not towards lactose. β -Gal II activity was at least 20-fold higher when cells were grown on TOS than when cells were grown on galactose, glucose and lactose (Van Laere et al., 2000).

β -1,3-Galactosyl-N-acetylhexosamine phosphorylase, a new enzyme from *B. bifidum*, which catalyzed the reversible phosphorolytic cleavage of β -1,3-galacto-oligosaccharides, has been characterized (Derensy-Dron et al., 1999).

The presence of β -fructofuranosidase, which degrades fructo-oligosaccharides, from some strains of Bifidobacterium was recently investigated. This enzyme differs (in terms of relative activity towards different substrates) from yeast invertases (Muramatsu et al., 1992).

A new β -fructofuranosidase has been isolated from *B. infantis* (Imamura et al., 1994). This enzyme catalyzes the hydrolysis of sucrose, 1-ketose, nystose, inulin and raffinose, but does not catalyze the hydrolysis of maltose or cellobiose, indicating that this fructo-oligosaccharides enzyme is a novel type of β -fructofuranosidase.

Some enzymes are species-specific. Experimental studies carried out by Crociani et al. (1994) have shown that only *B. bifidum* may degrade intestinal gastric mucin. In the same study, it also has been observed that two out of three species found in the oral cavity, *B. denticoles* and *B. inopinatum*, are able to degrade dextran. From *Bifidobacterium* spp. isolated from dental caries, an extracellular dextranase (EC 3.2.1.11) was partially characterized. This extracellular enzyme, which is able to degrade α -D-(1 \rightarrow 6) linkages of dextrans, uses an endohydrolytic mode of cleavage as it is able to liberate saccharides larger than 1 glucose unit (Kaster and Brown, 1983).

Knowledge of the enzymatic network of bifidobacteria, the study of which is expanding, may help to better understand the mechanisms by which probiotic organisms may exert health effects.

NUTRITION Most species of the genus *Bifidobacterium* are able to utilize ammonium salts as their sole source of nitrogen (Hassinen et al., 1951), but *B. suis*, *B. magnum*, *B. choerinum*, *B. cuniculi* and *B. pseudolongum* subsp. *globosum* do not grow without organic nitrogen (Matteuzzi et al., 1978; Mattarelli and Biavati, 1999a). In an organic nitrogen-free medium, considerable amounts of various amino acids are excreted by strains of *B. thermophilum*, *B. adolescentis*, *B.*

dentium, *B. animalis* and *B. infantis*. Generally the amino acids produced in the largest amounts are alanine, valine, and aspartic acid. Exceptionally, *B. bifidum* can produce up to 150 mg/liter of threonine (Matteuzzi et al., 1978).

Analogue-resistant mutants obtained from *B. thermophilum* (*B. ruminale*) showed increased production of isoleucine and valine (Crociani et al., 1977; Matteuzzi et al., 1976). Homoserine dehydrogenase and threonine deaminase activities as well as some aspects of their regulation have been studied in many species of the genus (Selli et al., 1986).

Studies on nutrition of plasmid-negative and -positive clones of *B. globosum* (now named "*B. pseudolongum* subsp. *globosum*") have revealed the auxotrophy for L-methionine for both clones (Mattarelli and Biavati, 1999a). The auxotrophy for L-leucine, shown only for plasmid-positive clones, pointed out the involvement of plasmids in this requirement. The lack of β -isopropylmalate dehydrogenase enzyme activity is considered responsible for the L-leucine auxotrophy in the plasmid-positive clones (Mattarelli and Biavati, 1999b). Minimal amino acid requirements were investigated. Only six or seven amino acids were required for growth, regardless of the ones chosen, including L-leucine and/or L-methionine for plasmid-positive and -negative clones, respectively.

A survey of vitamin and growth factor requirements was made in 10 species of bifidobacteria. The different species showed a great deal of heterogeneity (Trovatelli and Biavati, 1978). Comparative studies on the synthesis of water-soluble vitamins (thiamine, folic acid, nicotinic acid, pyridoxine, cyanocobalamin and riboflavin) among 24 strains of five species isolated from human feces have shown that many strains can synthesize all of the vitamins tested, with the exception of riboflavin. The concentration of the vitamins accumulated varied widely among different species or strains (Deguchi et al., 1985). Noda et al. (1994) have also demonstrated the ability of bifidobacteria to synthesize biotin.

Some factors called "bifidus factor" (BF) able to stimulate the growth of bifidobacteria have been studied in *B. bifidum*. The BF discovered by Petuely and Kristen (1953) is nothing but lactulose that, if added to milk, produces an increase in intestinal bifidobacteria. Actually, we cannot speak of a specific BF because Terada et al. (1992) found that also the number of *Lactobacillus* and *Streptococcus* increases. It should be noted that this molecule is active only in vivo.

The BF1 factor is a complex of oligosaccharides present in the milk of women and also, in minor portions, in the milk of several other mammals (Gyorgy et al., 1954a; Gyorgy et al., 1954b).

These oligosaccharides have been classified into two groups, neutral and acidic. The "bifidogenic" activity is proportional to the number of *N*-acetylglucosamine residues contained in the oligosaccharide (Von Nicolai and Zilliken, 1972). The BF2 factor is a proteolysate specifically obtained from bovine casein hydrolysis by trypsin, pancreatic or papain (Gyorgy and Rose, 1955; Rose and Gyorgy, 1963). A total acid hydrolysis totally inactivates casein hydrolysate (Seka Assy, 1982). Proteins and oligosaccharides also are classified as "bifidogenic factor." In the former case, the glycoproteins contained in human colostrum (Hirano et al., 1968) and in bovine colostrum (Nichols et al., 1974) help the growth of bifidobacteria. Even lactoferrin, an iron-binding protein, promotes the growth of bifidobacteria. The study by Petschow et al. (1999) suggests that bovine lactoferrin from mature milk increases the growth of *B. infantis* and *B. breve* in a dose-dependent way in vitro, whereas human lactoferrin promotes the growth of *B. bifidum* but not that of *B. infantis* and *B. breve*. Among the numerous oligosaccharides, soybean oligosaccharides, which consist mainly of the trisaccharide raffinose and the tetrasaccharide stachyose (Benno et al., 1987; Hayakawa et al., 1990; Yazawa et al., 1978), stimulate the growth of bifidobacteria. More recently, other oligosaccharides have been identified and termed "bifidogenic factors," such as fructo-oligosaccharides (FOSs; Gibson and Wang, 1994; Roberfroid et al., 1998b), synthetic oligosaccharides, and transgalactosylated oligosaccharides (TOSs; Bouhnik et al., 1997; Ito et al., 1993). Gluco-oligosaccharides (GOSs) also stimulate the growth of bifidobacteria although less intensely than FOSs and TOSs do (Djouzi and Andrieux, 1997; Jaskari et al., 1998). The polysaccharide inulin also increases fecal bifidobacteria, having a similar prebiotic effect of oligofructose (Gibson and Roberfroid, 1995). In conclusion, the "bifidogenic factors" can be classified in two large groups: oligosaccharides and protein hydrolysates. In recent years, the need of bifidus factors for growth has been questioned because it is possible to obtain bifidobacteria multiplication in the absence of these factors. Therefore, they cannot be defined as growth factors.

The metalloelement requirements in *B. bifidum* have been extensively studied by Bezkorovainy and colleagues (Bezkorovainy and Topouzian, 1983; Bezkorovainy et al., 1986; Bezkorovainy et al., 1987; Topouzian et al., 1984). They examined the aspects of iron metabolism and the mechanisms of iron uptake that do not depend on siderophore-type carriers but on a proton-motive-force-associated electrogenic pump or pumps. There is hope that these investigations, which are important for bifidobacterial

ecology, will be extended to other species of the genus.

UREASE ACTIVITY In a study on the urease activity of more than 400 strains representing 21 species of bifidobacteria, the strongest ureolytic activity was found for most *B. suis* strains and only a few *B. breve*, *B. magnum* and *B. subtilis* strains. High levels of urease activity were present in cells grown in the absence of urea, suggesting that this enzyme is not inducible (Crociani and Matteuzzi, 1982).

Hatanaka et al. (1987) have shown that glutamate dehydrogenase and glutamine synthetase, only found in *B. adolescentis*, *B. bifidum*, *B. breve*, *B. infantis*, *B. longum*, *B. pseudocatenulatum* and *B. thermophilum*, may be involved in ammonia intake.

NITRATE REDUCTION *Bifidobacteria* usually do not reduce nitrates. However, cells grown in the presence of lysed cells may be capable of nitrate reduction. Cytochromes *b* and *d* are synthesized under these growth conditions (Van der Wiel-Korstanje and De Vries, 1973).

RESISTANCE TO ANTIBIOTICS AND OTHER BACTERICIDAL SUBSTANCES The antimicrobial susceptibility of 459 strains of bifidobacteria representing 15 species was determined by the broth dilution method. Penicillin G, erythromycin, clindamycin, vancomycin, bacitracin, chloramphenicol and lincomycin were the most active compounds. Resistance to polymyxin B, nalidixic acid, kanamycin, gentamicin, and metronidazole was a common feature among the fifteen species studied. Neomycin, streptomycin and tetracycline had the most variable activity (Matteuzzi et al., 1983). In a study by Charteris et al. (1998) on 15 human bifidobacterial strains and one strain of *B. animalis*, the same results were obtained except for vancomycin susceptibility. In this study, vancomycin resistance was observed as a general characteristic, opposite to what Matteuzzi et al. (1983) had found. This difference may be due to divergent assay methodologies inasmuch as vancomycin is reported to diffuse poorly in agar media (Thomson et al., 1995). The *b*-lactamase activity of four microorganism-drug combinations was evaluated. Its absence suggested that cell-wall impermeability was responsible for cephalosporin resistance among bifidobacteria (Charteris et al., 1998).

Mangin et al. (1999), using rRNA gene restriction analysis, carried out an in vivo study on the influence of antibiotics on bifidobacterial microflora. The predominant bifidobacterial strains of intestinal flora in four human subjects were monitored before and after eight days of treatment with oral amoxicillin-clavulanic acid (Augmen-

tin). These antimicrobial agents are known to strongly inhibit bifidobacteria (Dubreuil et al., 1996). The combination of amoxicillin and clavulanic acid did not involve significant long-term changes in predominant bifidobacterial populations of intestinal flora, as was the case when rifampicin and streptomycin were administered (Mangin et al., 1999). Members of the normal bifidobacterial flora cannot be eradicated by these antimicrobial treatments. The antimicrobial effect is probably dose-related and removal of the antibiotic allows prompt regrowth of their population.

Encouraging results also have been obtained through the use of essential oils as antimicrobial agents against some species of bifidobacteria (Biavati et al., 1997; Crociani et al., 1997).

BACTERIOCIN PRODUCTION Bacteriocins have the potential to inhibit growth of pathogens and to prevent microbial food spoilage. The bactericidal action of bifidobacteria is ascribed to the production of some kind of antimicrobial agent in addition to their pH-reducing effect (Fujiwara et al., 1997; Gibson and Wang, 1994; Meghrous et al., 1990). Bifidocin B, for example, is a bacteriocin produced by *B. bifidum* NCTB 1454; it has a broad antimicrobial spectrum, inhibiting the growth of species of *Listeria*, *Enterococcus*, *Bacillus*, *Lactobacillus*, *Leuconostoc* and *Pedococcus* (Yildirim and Johnson, 1999). The finding could be very important in the exploitation of bifidobacteria as biopreservatives, i.e., preventing growth of pathogens or contaminating bacteria present in food.

Genetics

The genetic analysis and manipulation of bifidobacteria are very important to better understand their phylogeny and probiotic roles. However, the genetic work on bifidobacteria is quite new. Initially, the work by Sgorbati et al. (1982b) reported the presence of plasmids in members of the genus *Bifidobacterium*. Plasmids were found in *B. longum*, the predominant species in the human intestine, in *B. pseudolongum* subsp. *globosum*, the most common *Bifidobacterium* species in animals, and in *B. asteroides* and *B. indicum*, species found exclusively in the Western and Asiatic honeybee hindguts, respectively. *Bifidobacterium infantis*, the species most closely related to *B. longum*, did not carry plasmids, although strains of both species, generally isolated from the same specimens, were studied; the same was true for the 45 strains studied as *B. infantis*-*B. longum* "intermediates" found in calf feces. Other "human" bifidobacteria species, i.e., *B. dentium*, *B. breve*, *B. bifidum*, *B. pseudocatenuatum* and *B. catenulatum*, were found to be plas-

mid-free. In *B. breve*, however, the presence of plasmids with 5 different profiles has been shown by Iwata and Morishita (1989). Strains of *B. longum* may harbor defective lysogenic phages, but no apparent correlation exists between the presence of plasmids and the production of phages induced by UV or mitomycin C (Sgorbati et al., 1982b; Sgorbati et al., 1983). Preliminary data on structural relatedness among plasmids were obtained by means of blot hybridization using many selected, unrestricted plasmid probes. Seven different plasmids were found in *B. longum* (123 strains), 13 in *B. asteroides* (70 strains), three in *B. pseudolongum* subsp. *globosum* (28 strains), and three in *B. indicum* (73 strains). The frequency and distribution of such plasmids among samples and geographical areas (*B. asteroides* and *B. indicum*) were reported (Sgorbati et al., 1986a; Sgorbati et al., 1986b). In *B. pseudolongum* subsp. *globosum*, auxotrophy for L-leucine has been detected in plasmid-positive but not -negative clones. The conclusion of this study is that the presence of the plasmid confers the negative feature of auxotrophy for L-leucine.

From human intestinal bifidobacteria, only *B. longum* and *B. breve* have been shown to possess plasmids (Sgorbati et al., 1982b; Iwata and Morishita, 1989). All the plasmids so far investigated are cryptic. Few plasmids (pVS809 [Mattarelli et al., 1994], pMB1 [Rossi et al., 1996], pCIBb1 [O'Riordan and Fitzgerald, 1999] and pKJ50 [Park et al., 1999b]) have been characterized. Since these first observations, other studies have been carried out. Vectors capable of transfecting many bifidobacteria and with distinct replication origin and markers for *Escherichia coli* have been described (Missich et al., 1994; Park et al., 1997; Rossi et al., 1996; Rossi et al., 1998) as being derived from the small cryptic plasmid pMB1 or others (Matsumura et al., 1997). Initially, the transformation efficiency of many bifidobacteria with these plasmids was very low; recent developments (Argnani et al., 1996) have considerably increased transformation efficiency for all strains tested so far.

Numerous sequences of bifidobacteria belonging to a large part of the described species are deposited at international data banks (European Molecular Biology Laboratory [EMBL] and GenBank).

Ecology

BIFIDOBACTERIA IN HUMANS GASTROINTESTINAL TRACT. The microbial succession in the human and animal alimentary tract in the first weeks of life is similar even if newborn animals are exposed to a greater number of microorganisms compared to human newborns. In the first few days of life, microbiota are characterized by

coliforms and streptococci. Soon clostridia, *Bacteroides* and lactobacilli appear. Microbial colonization proceeds via a constant succession of species and the occurrence of substantial changes in the appearance of the microbiota after weaning. Biota succession was studied in several animals (Moughan et al., 1992; Smith, 1965). In most of these studies, fecal samples were examined. Rarely were samples taken from several areas of the gastrointestinal tract. Autochthonous microorganisms were almost never distinguished from allochthonous ones, even though this distinction is very important to avoid being led astray in the interpretation of the presence of the several microbial types. The study of microbial successions is difficult because of the extreme variability contributed by great variation in rearing and feeding practices and by the limitations in the sampling and analysis of the intestinal microbial communities. Microbial colonization is regulated by: 1) external factors such as microbial change of the surrounding environment, food and eating habits, composition of maternal microbiota, diet and heat stress; 2) host-related factors such as endogenous nutrients, the physiology of the host and microbiota; and 3) factors inherent to microorganisms such as adhesive features and resistance to an acid environment (e.g., the stomach). The mechanism by which the intestine selects a limited number of species from the vast array of microbes with which it comes in contact is still unknown. The ability to degrade complex carbohydrates generated by the host epithelium, such as mucin, is restricted to a few species of the intestinal microflora. Therefore, bacteria such as bifidobacteria and *Ruminoccus*, which are able to hydrolyze oligosaccharide chains, are positively favored in the colonization.

The succession of microbial communities in the human gastrointestinal tract is amongst the most widely studied. Within the first 24 hours,

E. coli and *Streptococci*, which reach a level of 10^8 – 10^{10} per g of feces, colonize the gastrointestinal tract of all newborns. These bacteria create a reduced environment favorable to the settlement of anaerobic species such as *Bacteroides*, *Bifidobacterium*, *Clostridium* and *Lactobacillus*. In breast-fed newborns, the number of *E. coli*, streptococci, *Bacteroides* and *Clostridium* decreases, whereas the group of bifidobacteria becomes dominant. The distribution of the various microbial groups in the intestinal microbiota of breast-fed or bottle-fed infants is shown in Fig. 13. Once dietary supplementation begins, the microbiota of breast-fed infants become similar to those of bottle-fed infants in which bifidobacteria are not dominant. After solid food introduction and weaning, breast-fed and formula-fed infants have similar fecal microbiota, which resemble those of an adult by about the second year of life (Conway, 1997). The distribution of the major microbial groups in adult microbiota is shown in Fig. 14. Generally, fecal microbiota

Fig. 14. Distribution of the major microbial groups in the fecal flora of human adults. Data from Mitsuoka and Kaneuchi, 1977; Finegold et al., 1983; Mata et al., 1969.

Fig. 15. Distribution of bifidobacterial species in the feces of breast-fed and bottle-fed infants. Data from Biavati et al. (1986).

fluctuations are greater in children with larger day-to-day variations in diet than in adults. Relatively small amounts of formula supplementation of breast-fed infants shift the pattern from a breast-fed to a formula-fed one. A great variation in the distribution of bifidobacteria has been observed. Some infants have no detectable bifidobacterial flora until solid food is introduced, with more formula-fed infants (38%) than breast-fed infants (16%) lacking bifidobacteria. In general, infants in whom no bifidobacteria are detected have a high number of *Bacteroides*, clostridia and *E. coli* (Stark and Lee, 1982).

Succession of the microbiota in the intestinal tract at the group level as determined by selective enumeration gives no indication about the distribution of species and strains.

Concerning species distribution, previous studies showed that *B. breve* and *B. infantis* are species typical of breast-fed or formula-fed infants whereas *B. adolescentis* was typical of children, adults and elderly people (Benno et al., 1984; Biavati et al., 1984; Biavati et al., 1986; Mitsuoka, 1984). *Bifidobacterium breve* was the dominant species in breast-fed infants, whereas *B. longum* and *B. adolescentis* were more frequent in formula-fed infants (Mevisen-Verhage et al., 1987; Fig. 15). *Bifidobacterium pseudocatenulatum*, *B. longum* and *B. adolescentis* are dominant in adults (Biavati et al., 1986; Fig. 16). This is consistent with the concept that supplementation of infant formula initiates the development of a microbiota more closely resembling the adult profile (Conway, 1997). In agreement with previous data (Biavati et al., 1986), a recent study of bifidobacterial species distribution by Matsuki et al. (1999) using

Fig. 16. Distribution of bifidobacterial species in the feces of human adults. Data from Biavati et al. (1984).

species-specific PCR primers showed that the *B. catenulatum* was the most common of the adult intestinal bifidobacterial flora (detected in 44 of 48 samples [92%]), followed by *B. longum* and *B. adolescentis*, and that *B. breve*, *B. infantis* and *B. longum* were frequently found in the intestinal tracts of infants.

Regarding the presence of simple or complex bifidobacterial microflora at the species level, the study of Biavati et al. (1986) reveals that 5 of 11 subjects examined had one species of bifidobacteria, whereas the remaining 6 subjects had two, three or four species.

The fine-tuning of molecular techniques (molecular probes, ribotyping, PFGE, etc.) gave

great impulse to the study of microbial ecology, allowing monitoring of single strains of intestinal microflora.

In a recent study of fecal samples collected from 10 human subjects, analysis by pulsed-field gel electrophoresis and ribotyping revealed that the collection of bifidobacterial strains in feces of each subject was unique. Only one strain was detected in two different subjects. A "simple" bifidobacterial microflora, arbitrarily defined as a collection of four or fewer bifidobacterial strains, was found in five of the ten subjects studied, whereas the other subjects had a "complex" (more than four bifidobacterial strains) microflora. Complexity or simplicity of the bifidobacterial flora was not related to gender. In this study, the strains were characterized by pulsed-field gel electrophoresis and ribotyping but not classified (Kimura et al., 1997). Studies based on Southern analysis using ribosomal 23S DNA probes confirmed that bifidobacterial microflora is typical of each individual, with the possible coexistence of several species in the same flora (as already observed in previous studies) and even several distinct strains of the same species (up to three different *B. longum* or *B. adolescentis* for one subject; Mangin et al., 1999). Although the fecal microflora of adult humans shows considerable stability in composition at the level of bacterial population both over time and in response to variation of diet, dominant species and strains may be subjected to variations (Stark and Lee, 1982). Studies regarding the fluctuations within populations of bifidobacteria as well as other bacterial groups are scarce. A monitoring of the bifidobacterial fecal population of two humans over 12 months showed that one subject had a remarkably stable microfloral population with one strain predominating, whereas the other had a more dynamic microflo-

ral population with varying strain composition (McCartney et al., 1996). The proportion of the human population harboring a stable simple bifidobacterial flora compared to that harboring a complex, dynamic microflora at the strain level is not known. It is possible that subjects with a complex and dynamic microflora are more easily colonized by exogenous bifidobacteria; however, studies in this field are limited and a complete knowledge of these complex phenomena is lacking. Such knowledge might determine a more rational use of probiotics and prebiotics. The studies carried out so far on the introduction of exogenous bifidobacteria (probiotics) through diet confirm the stability of intestinal microbiota; in fact they remain only during the period of ingestion to gradually decrease until they disappear a few days after treatment. Even with antibiotic treatment, such as the combination of amoxicillin and clavulanic acid, which substantially decreases the bifidobacterial microflora, the intestinal microflora regrows to normal levels with the same members about two months after the antibiotic treatment ends (Mangin, 1999). In general, we may conclude that each individual, apart from the dramatic biological succession that occurs in the digestive tract following birth and terminating before childhood, has a microflora stable in time as far as the anaerobic genera are concerned. Microflora in some humans may be subject to fluctuations as far as species or most important strains are concerned. Even in advanced age, a substantial deviation (Fig. 17) from the adult microfloral composition may occur, probably as a result of physiological and alimentary changes of the host. Studies on microbial ecology are therefore still in their initial stages and several questions are awaiting a clearer answer. A more in-depth knowledge of microbial ecology of the digestive

Fig. 17. Changes in distribution of some groups of the intestinal microbiota in humans from birth to old age. Data from Mitsuoka and Kaneuchi (1977); Finegold et al. (1983); Kleessen et al. (1995); Harmsen et al. (1999).

tract will improve the selection of probiotics and prebiotics.

ORAL CAVITY. More than 300 species have been isolated in the oral cavity, although in healthy subjects this number is 50–100. Bifidobacteria are very early colonizers of the gastrointestinal tract and are regularly present in the oral cavity of children. Later they can become normal inhabitants of the adult dental plaque. However, these microorganisms have been isolated only a few times in the oral cavity, probably due to the use of inappropriate methods of isolation. In one study, they were isolated in the saliva of only one of 10 subjects and none were found to host bifidobacteria in their gingival spaces (Sanyal and Russell, 1978). Other researchers were able to show that 7 out of 62 isolates in gingival spaces were bifidobacteria. They fermented esculin and were identified as *B. adolescentis* (Maeda, 1980). Bifidobacteria were found also in the dental plaque, accounting for 6% of all the isolates (Kolenbrander and Williams, 1981). In his work on oral microflora, Sutter has stressed the difficulty in having careful bacterial profiles from the different parts of the oral cavity (Sutter, 1984). In this habitat the presence of bifidobacteria is underestimated owing to the use of inappropriate media and methods of identification. Scardovi and Crociani (1974a) and Crociani et al. (1996b) specifically looked at oral bifidobacterial microflora and found their presence was almost constant.

The species *B. dentium* was isolated from dental caries in 1974 (Scardovi and Crociani, 1974a). In 1996, a new study about dental caries led to the isolation and identification of two new species from this habitat: *B. denticolens* and *B. inopinatum* (Crociani et al., 1996b). *Bifidobacterium inopinatum* displays a very unusual morphology and a very low G+C mol% value compared to the other species of bifidobacteria. The samples studied highlighted the presence of one or more out of the three species.

VAGINA. Few studies are present in the literature dealing with the presence of bifidobacteria in vagina. From available data, bifidobacteria are present in 22–26% of healthy women (Werner and Seeliger, 1963; Crociani et al., 1973), but no epidemiological data are available on vaginal bifidobacteria. *Bifidobacterium breve* and *B. adolescentis* have been the most frequently isolated species, whereas *B. longum* and *B. bifidum* were present to a smaller extent (Werner and Seeliger, 1963; Crociani et al., 1973; Korschunov et al., 1999). In this habitat, bifidobacteria could play a role in maintaining vaginal homeostasis by producing organic acids and bacteriocins antagonistic towards pathogens.

Korschunov et al. (1999) proposed the use of bifidobacterial strains as probiotics in the correc-

tion of the microflora of the urogenital tract in females.

HYPOCHLORHYDRIC STOMACH. Interesting data have emerged from studies of the hypochlorhydric stomach by autoimmune atrophic gastritis or by omeprazole treatment; *B. denticolens*, *B. inopinatum*, *B. dentium* (the same species found in the oral cavity), but also “*B. infantis-longum*,” colonize this habitat, pointing out that the hypochlorhydric stomach represents a new ecological niche different from all the others of the body (Brandi et al., 1996).

BIFIDOBACTERIA IN ANIMALS Studies of intestinal microflora were performed mainly on domestic animals and revealed a complex microflora: *Bacteroides*, eubacteria, anaerobic lactobacilli, anaerobic Gram-positive cocci, spirillaceae and often bifidobacteria. Bifidobacteria are present in almost all chickens, dogs, pigs, rats and hamsters even if less abundantly than lactobacilli, whereas in monkeys and guinea pigs, the amount of bifidobacteria is greater than the amount of lactobacilli. Mice, rabbits and horses rarely display bifidobacteria, and cats and minks never have them (Mitsuoka and Kaneuchi, 1977). The composition of bifidobacteria microflora in animals varies with the age, species and diet of the host.

Some species apparently are host-specific: *B. magnum* and *B. cuniculi* have only been found in rabbit fecal samples, *B. pullorum* (Trovatelli et al., 1974) and *B. gallinarum* (Watabe et al., 1983) only in the intestine of chickens and *B. suis* only in piglet feces (Matteuzzi et al., 1971; Fig. 7).

Feces of suckling calves and breast-fed infants harbor the same bifidobacterial species (the only case where species typical of humans also are found in animals), except for a group of 180 strains isolated from the feces of suckling calves that could not be identified as members of a species because of their high degree (over 80%) of DNA homology with both *B. infantis* and *B. longum*. These strains are referred to as “intermediate” between the two species (Scardovi et al., 1979a) pending a definition of their taxonomic status.

Bifidobacterium asteroides is the only species found in *Apis mellifera* intestine, irrespective of the geographical area of origin (Scardovi and Trovatelli, 1969a), whereas *A. cerana* and *A. dorsata* (from the Philippines and Malaysia) harbor specific biovars of the species *B. indicum* that have different transaldolase isozymes but are indistinguishable by DNA-DNA hybridization (Scardovi et al., 1979a). Such subtle dependence on host phylogenetic position was heretofore unsuspected. Furthermore, *B. asteroides* and *B. indicum* in the loci studied so far, using the zymo-graph technique, are much more variable than

any other species of *Bifidobacterium* (Scardovi et al., 1979a). The exogenous and/or endogenous factors controlling this variability should be further studied.

Among the large biodiversity of animals, only a few species have been considered for studies of the intestinal microflora. The isolation of bifidobacteria from honeybees, whose significance and origin in the gut are at present unknown, could form an interesting chapter of insect microbiology if they could be found elsewhere in this class of animals. In conclusion, the study of bifidobacteria ecology is at its starting point, and interesting aspects of probiotics use in animals could stimulate its investigation.

BIFIDOBACTERIA IN *EXTRA*-BODY ENVIRONMENTS

Bifidobacteria are found in *extra*-body environments only as a consequence of fecal contamination. They can be considered to be useful indicators of human and animal fecal pollution when they are correctly identified (Mara and Oragui, 1983). A study of 75 samples from a highly contaminated stream near Bologna (Italy) reveals that *B. longum*, *B. adolescentis*, *B. pseudocatenulatum*, *B. catenulatum* and *B. thermophilum* are the most representative species, whereas *B. globosum*, *B. angulatum*, *B. breve*, *B. animalis*, *B. choerinum*, *B. subtile* and *B. minimum* occur only in low numbers (Crociani et al., 1996a). Field data from Rhodes and Kator (1999) indicate a better likelihood of bifidobacteria recovery from cool (10°C) than from warm water (23–30°C).

Bifidobacteria can be considered also as indicators of fecal contamination in meat and meat products. The conventional indicator, *E. coli*, does not provide any information on the origin of fecal contamination; this can be obtained by identifying the species of bifidobacteria that are present. The study of Gavini and Beerens (1999) showed the presence of bifidobacteria of animal origin in meat and meat products, except for 4% of strains of human origin, is due to artificial contamination of meat by manual handling.

Disease

Bifidobacteria have been occasionally isolated from infective material (Biavati et al., 1982), and although implicated in some opportunistic infections (Miller-Catchpole, 1989), they are generally regarded as nonpathogenic. Predisposing factors such as ongoing infections (Prévot et al., 1967) or contact with contaminated material (Ha et al., 1999) may favor finding bifidobacteria in association with infections. Some strains of bifidobacteria also have been reported to participate in soft-tissue infections initiated by mixed populations. These include some strains of bifi-

dobacteria associated with peritonitis, dental pyorrhea and various abscesses (Prévot et al., 1967; Biavati et al., 1982). Only species isolated from the dental caries and plaques, *B. dentium*, *B. denticolens* and *B. inopinatum*, appear to have the most pathogenic potential in cariogenic processes. The role played by bifidobacteria in this pathology is still unclear. *Bifidobacterium* species of the oral cavity are in fact capable of degrading dextran, an important component of plaque, which plays a crucial role in the colonization of a potential cariogenic organism such as *Streptococcus mutans*. Therefore in this light, bifidobacteria may be antagonists of the cariogenic process, impairing plaque formation. On the other hand, bifidobacteria produce acids, which may damage the enamel and cause cariogenic phenomena.

Applications

PROBIOTIC The “probiotic” concept, referring to consumption of live microbes, mainly lactic acid bacteria and bifidobacteria, to improve the health and well-being of the host, dates back to Metchnikoff (1907). The term was used for the first time by Parker (1974) to describe “every substance or microorganism that contributes to gastrointestinal balance.” Over time, the meaning of the term was slightly changed. In fact Fuller (1989) describes it as “a live microbial feed supplement which beneficially affects the host animal by improving its microbial balance.” This definition stresses the importance of viability and avoids the use of the too broad term, “substances,” which could even include antibiotics. Such a term has been used by Haavenar and Huis in’t Veld (1992) to describe a “mono- or mixed culture of live microorganisms which, when applied to animal or man, beneficially affect the host by improving the properties of the indigenous gastrointestinal microflora.” In recent years, there has been a tendency to widen the concept of probiotics to apply not just to the gastrointestinal tract but to other mucous surfaces such as the urogenital tract and the upper respiratory tract and to use such a term as a synonym for “biotherapy,” which means a therapy of microorganisms with antagonistic activity towards pathogens (Elmer et al., 1996).

The composition of the intestinal microflora is important for the well-being of the host although its precise functions are very difficult to study. Probiotic microorganisms, mainly lactobacilli and bifidobacteria, which influence the composition of bacterial microflora, may play an important role in the prophylaxis and therapy of gastrointestinal diseases. The main effects of probiotics on the host with particular reference to bifidobacteria (Fig. 18) are as follows.

- Regulation effect of the gut microflora
- Production of antimicrobial substances
- Alleviation of lactose intolerance
- Enhancement of immune system
- Anticarcinogenic activity
- Production of vitamins

Fig. 18. Benefits contributed by bifidobacteria to their host.

ALLEVIATION OF LACTOSE INTOLERANCE. Bifidobacteria may alleviate lactose intolerance (Rimbaud, 1990), both directly by providing β -galactosidase and indirectly by lowering the pH of the environment, thereby contributing to growth of the intestinal microflora that produce β -galactosidase (Jiang et al., 1996; Jiang and Savaiano, 1997; Vesa et al., 1996). The decrease of bifidobacteria appeared to be at least in part responsible for the lower β -galactosidase activity in patients with active or quiescent Crohn's disease. An alternative therapy for Crohn's disease is to increase the bifidobacterial counts in the human colon (Favier et al., 1997).

PREVENTION OF DIARRHEA. In the human large intestine, the microflora coexist in constant balance (Macfarland and Cumming, 1991). Occasionally homeostasis may be upset by an invasion of microorganisms which are not part of the host flora. This alteration may induce diarrhea (a serious problem in the world), which is often a manifestation of acute inflammation. The microorganisms present in the microflora protect the host from pathogens thanks to the formation of a front-line mucosal defense. In fact autochthonous intestinal bacteria prevent intestinal colonization by pathogenic bacteria by directly competing with them for essential nutrients or for epithelial attachment sites. Moreover, thanks to the production of antimicrobial compounds and volatile fatty acids, bifidobacteria create unfavorable environmental conditions for the growth of many enteric pathogens. Gibson and Wang (1994) have shown that the antagonistic effect of a low pH environment on the growth of *E. coli* and *Clostridium perfringens* may not be the sole mechanism of inhibition. Bifidobacteria in fact were able to excrete some inhibitory factors having bactericidal or bacteriostatic action towards a range of both Gram-positive and Gram-negative potentially pathogenic bacteria. These inhibitory factors, also called "bacteriocins," are being studied (Yildirim and Johnson, 1999).

Recent studies have shown that some lactobacilli and bifidobacteria preparations may have potential in controlling diarrhea and intestinal side effects of radiation (Korschunov et al., 1996). *Bifidobacterium longum* decreased the level of fecal clostridial species and reduced the frequency of erythromycin-associated diarrhea (Colombel et al., 1987). Orrhage et al. (1994a) have shown that supplementation with a combination of *B. longum* and *Lactobacillus acidophilus* reduced the ecological changes in the intestinal microbiota induced by administration of clindamycin. Some strains of *Bifidobacterium* spp. have been shown to inhibit the multiplication of *Clostridium difficile* in vivo (Rolfe et al., 1981). The feeding of a formula supplemented with *B. bifidum* and *Streptococcus thermophilus* substantially reduces the incidence of acute diarrheal disease in infants (Hoyos, 1999) and the rate of rotaviral shedding (Saavendra et al., 1994). Moreover, Yasui et al. (1999) described one strain of *B. breve* that activates the humoral immune system and can protect against rotavirus infection and influenza infection in infants. These findings are in agreement with animal-model studies. Mice infected with rotavirus have shown a passive protection against the virus when fed with *B. breve* (Yasui et al., 1995) or *B. bifidum* (Duffy et al., 1993). *Bifidobacterium animalis* also provided protection of immunodeficient mice against mucosal and systemic candidiasis (Wagner et al., 1997); it also plays a protective action against damage to intestinal villi induced by low zinc diets (Mengheri et al., 1999). Yasui et al. (1999) suggest the use of *B. breve* YIT4064 as a live antigens-delivery-vehicle for oral vaccines to various pathogens.

ENHANCEMENT OF IMMUNE SYSTEM. Bifidobacteria are able to enhance several immune functions: activation of lymphocytes and macrophages (Hatcher and Lambrecht, 1993; Sekine et al., 1994) and stimulation of antibody production as well as the mitogenic response in Peyer's patches (Kado-oka et al., 1991; Lee et al., 1993; Takahashi et al., 1993; Yasui and Ohwaki, 1991). This stimulation of the immune response by bifidobacteria seems to be mediated by the ability of bifidobacteria to induce the production of cytokines (Marin et al., 1996). Cytokines are protein mediators involved in all aspects of immunoregulation. Bifidobacteria are able to stimulate macrophages and helper-T cells to produce tumor necrosis factor- α and interleukins, respectively, when tested in vitro (Marin et al., 1996; Park et al., 1999a). The ability to induce cytokine production seems to be strain-dependent (Park et al., 1999a). Bifidobacteria also can induce production of large quantities of IgA in vitro using a Peyer's patch cell culture method (Yasui et al., 1992). If the IgA

produced in vitro is also important in vivo, this could justify the use of bifidobacteria as a probiotic therapy able to build and stimulate an immunological barrier to foreign material, particularly pathogenic microorganisms, allergenic food proteins and carcinogens (Majamaa and Isolauri, 1997).

CANCER PREVENTION. Colorectal cancer is one of the leading causes of cancer morbidity and mortality in Western countries. Bifidobacteria have been shown to possess antimutagenic and anticarcinogenic properties. While there is no direct evidence for cancer suppression in humans, a wealth of indirect evidence is present in the literature, based on laboratory studies (Ishibashi and Shimamura, 1993; Kulkarni and Reddy, 1994; Mitsuoka, 1990; Rao et al., 1986; Singh et al., 1997).

In animal models of colon carcinogenesis, administration of *B. longum* as a lyophilized preparation was able to reduce azoxymethane-induced colon cancer as measured by the reduction in the number of aberrant crypt foci (Challa et al., 1997; Kulkarni and Reddy, 1994; Reddy, 1999; Singh et al., 1997) and tumor markers such as ornithine decarboxylase and in the expression of ras-p21 oncoprotein.

The precise mechanism by which bifidobacteria exert their antitumorigenic activity is not clear. A number of studies (Okawa et al., 1993; Orrhage et al., 1994b; Sekine et al., 1995; Zhang and Ohta, 1991; Zhang and Ohta, 1993) pointed out that the antimutagenic activity could reside in the cell wall.

The mechanism leading to tumorigenic suppression could comprise one or more of the following proposed events (Hirayama and Rafter, 1999): 1) enhancement of host immune responses; 2) direct binding and degradation of potential carcinogens; 3) alteration of intestinal microflora which produces putative carcinogens; 4) alteration of the physicochemical environment in the colon; and 5) production of antitumorigenic substances.

FEATURES OF BIFIDOBACTERIA FOR HUMAN CONSUMPTION. There is general agreement on the characteristics that probiotic microorganisms should possess to be useful for the host (Fig. 19):

1) They should survive in sufficient numbers to colonize or to persist in, albeit for short periods, the gastrointestinal tract and withstand the acidic gastric environment and bile acids as well as possess adhesion mechanisms to the intestinal mucosa. Regarding this issue, studies have been conducted on survival in an acidic environment (Biavati et al., 1992c) and bacterial adhesion (Bernet et al., 1993; Crociani et al., 1995; Dunne et al., 1999), which are important both to learn

- Microbial cells should be viable
- The strains used should belong to a species present in the specific habitat
- The strains used should colonize the specific habitat and have the ability to positively influence the host
- They should exhibit resistance to technological processes (i.e. lyophilization, etc.)
- Microbial cells should be administered together with substrates that promote their growth
- They should be nonpathogenic and nontoxic
- At least $15-20 \times 10^9$ microorganisms/day should be administered *

*This value represents approximately the content of a commercial yogurt preparation (125 ml)

Fig. 19. Important characteristics of "probiotic preparations" of bifidobacteria.

about the mechanisms that regulate such processes and to identify potentially probiotic strains.

2) They should be of human or animal origin depending on the intended use.

3) They should have the ability to positively influence the host and to colonize the specific habitat. Clinical trials need to be conducted to assess probiotic effects in normal humans and animals towards intestinal disorders and pathogenic conditions.

4) They should exhibit resistance to technological processes such as lyophilization and ease of obtaining a large microbial mass.

5) Microbial cells should be administered together with substrates that promote their growth.

6) They should be nonpathogenic and nontoxic.

7) At least $15-20 \times 10^9$ microorganisms/day should be administered (Zoppi et al., 1982).

Studies on potentially probiotic bifidobacteria carried both in vitro and in vivo highlight guidelines both for features of the strains and for the interactions with the host bacteria, which should lead to the best strains, thus creating a collection of strains adequate for probiotic use (Figs. 20 and 21).

BIFIDOBACTERIA AND THE HUMAN ENVIRONMENT. Several studies were conducted on fecal recovery of viable ingested probiotic bifidobacteria. The level of exogenous bifidobacteria was maintained as long as the probiotic preparation was consumed. After ingestion was stopped, the exogenous bifidobacteria gradually decreased and/or were no longer detectable eight days after cessation (Bouhnik et al., 1992; Biavati et al., 1995; Fig. 22).

In the development of alimentary and pharmaceutical probiotic products, bifidobacteria have been most commonly used in these last few years. Often, however, the bifidobacteria cur-

rently used in products for human consumption are not of human origin. Previous studies of dairy products such as yogurt, fermented milk, etc. showed the presence of *B. animalis*, which is known to live in animal habitats, in six different products sold in Europe (Biavati et al., 1992b) and in eleven out of sixteen products sold in Europe, Japan and the United States (Yaeshima et al., 1996). None of the products under study declared the presence of *B. animalis*. The product label instead provided the generic term *Bifidobacterium* spp. or a wrong specification such as *B. longum* or *B. bifidum*. In addition, in a recent study of an Italian pharmaceutical product, *B. animalis* was detected without being specified

(unpublished data). The difficulties of distinguishing *B. animalis* on the basis of common phenotypes together with the fact that *B. animalis* was described as a subspecies of *B. longum* are probably the main reasons for the presence of *B. animalis* as *B. longum* in many commercial fermented milk products. To avoid possible future mistakes in the use of bifidobacteria, strict identification methods should be applied (Biavati et al., 1992b).

Despite the generally acknowledged positive effects of bifidobacteria on human health, the basic mechanisms for this effect of probiotic microorganisms are still largely unknown. Food integrators, dairy products and pharmaceutical products that use probiotics will develop their full potential when a better knowledge of probiotic interaction with human microflora and the human gastrointestinal tract is gained. The development of *in vitro* and *in vivo* techniques to test the presence and survival of probiotics in the host intestine, the study of host immune system-probiotic interactions, the characterization of antimicrobial properties of probiotics and development of molecular biology techniques able to characterize both the probiotic and the resident intestinal microflora are crucial steps towards understanding probiotic physiology and ecology.

- Origin
- Resistance to environmental stress (acidity, temperature, oxygen, etc.)
- Fermentative capability
- Adhesion characteristics
- Presence of plasmids
- Productivity
- Genotypic and phenotypic stability

PREBIOTIC There are two approaches for increasing the number of health-promoting bacteria in the gastrointestinal tract: oral administration of live beneficial organisms (probiotics) and oral administration of dietary supplements (prebiotics) to selectively modify the composition of the microflora. Prebiotics have been defined (Gibson and Roberfroid, 1995) as “non-digestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon, that can improve the host’s health.”

The primary requirement of a prebiotic is that it has to be at least partially undigested and

Fig. 22. Human fecal concentration of exogenous and total bifidobacteria during and after ingestion of probiotic bifidobacteria. Data from Biavati et al. (1995).

unabsorbed in the small intestine to provide a fermentable substrate for the colon microflora. It also should stimulate the growth of health-promoting bacteria (mainly bifidobacteria and lactobacilli) and not that of the pathogenic bacteria (Gibson, 1998).

Prebiotics, acting differently from probiotics, can stimulate the growth of the host resident flora, allowing the proliferation of bacterial strains specific to the host instead of replacing them with new strains. Prebiotics not only increase the number of beneficial bacteria, but can also increase their metabolic activity, by supplying fermentable substrates (Roberfroid, 1998a).

The list of prebiotics employed up to now comprises di- and oligosaccharides, fructo- and galacto-oligosaccharides, soybean-oligosaccharides, inulin, resistant starch and other non-digestible oligosaccharides.

Some of the effects on host health of prebiotic administration are: 1) to increase colonization resistance (i.e., the ability to protect the host from exogenous intestinal pathogens; Oli et al., 1998); 2) to reduce risk factors associated with colon cancer (Reddy et al., 1997; Rowland et al., 1998); 3) to decrease serum lipid concentrations (Fiordaliso et al., 1995; Davidson et al., 1998); and 4) to enhance the uptake of minerals (Fiordaliso et al., 1995).

Gibson and Roberfroid (1995) have shown that a small alteration in diet by substituting sucrose (15 g/day) with oligofructose (15 g/day) or inulin may lead to significant increases in bifidobacteria. In particular, dietary supplementation of oligofructose has been shown to decrease a number of potential pathogens. Similar results were obtained by Bouhnik et al. (Bouhnik et al., 1996; Bouhnik et al., 1997), Sghir et al. (1998) and Kruse et al. (1999). It is important to remark that the administration of inulin can cause a moderate increase in gastrointestinal symptoms such as flatulence and bloatedness, whereas blood lipids and short-chain fatty acids remain unaffected (Kruse et al., 1999). In vitro investigation showed that the growth of bifidobacteria was stimulated by oligofructose and the related carbohydrate inulin. In addition, soybean oligosaccharide and transgalacto-oligosaccharides contribute to an increased fecal bifidobacteria number (Hayakawa et al., 1990).

SYNBIOTIC The modulation of host intestinal microflora may be regulated by the simultaneous administration of prebiotics (specific substrates) and probiotics (live microbial preparations). This combination goes under the name “synbiotics” (Collins and Gibson, 1999).

The beneficial effects generated by the presence of the probiotic organism and its immedi-

ately available specific substrate can be more than simply additive. In rat colon carcinogenesis, a single administration of bifidobacteria or oligofructose did not modify the formation of chemically induced aberrant crypts; protection was evident, though, when the synbiotics (bifidobacteria + oligofructose) were coadministered (Gallaher and Jinmo, 1999).

Genus *Gardnerella*

Phylogeny

The first data dealing with the phylogenetic relationships of the genus *Gardnerella* derive from Maidak et al. (1994). These researchers, using 16S rRNA sequencing, demonstrated the close relationship between *Gardnerella vaginalis* and the genus *Bifidobacterium* and grouped in one single taxon or division the type strain of the species *G. vaginalis* and the type strains of 19 species of the genus *Bifidobacterium*. Van Esbroeck et al. (1996) agree with this proposal and concluded that *Gardnerella* and *Bifidobacterium* represent distinct genera belonging to a single phylogenetic lineage. Phylogenetic grouping of these two genera is supported by the common feature of the presence of the enzyme fructose-6-phosphoketolase (Gavini et al., 1996). In 1997, Stackebrandt et al. described the new order Bifidobacteriales, which comprises the family Bifidobacteriaceae with the two genera *Gardnerella* and *Bifidobacterium* (Fig. 23).

Taxonomy

The taxonomy of genus *Gardnerella* was the object of many discussions during the past years, having been assigned to different genera such as *Haemophilus* and *Corynebacterium*.

Gardnerella vaginalis takes its name from H. L. Gardner, who was the first to describe the vaginitis associated with this organism; it was isolated for the first time by Leopold (1953) and it was described in the genus *Haemophilus vagina-*

1953 - First recognized by Leopold

1955 - Named *Haemophilus vaginalis* by Gardner and Dukes

1963 - Proposal of reclassification such as *Corynebacterium vaginale* by Zinnemann and Turner *Butyrivacterium* or *Propionibacterium* by Reyn et al.

1980 - Description of the new genus *Gardnerella* with the species *G. vaginalis* by Greenwood and Pickett and by Piot et al.

1997 - Stackebrandt et al. - New hierarchic classification; Order: Bifidobacteriales; Family: Bifidobacteriaceae; genera *Bifidobacterium* and *Gardnerella*

Fig. 23. Milestones of the taxonomy of *Gardnerella vaginalis*.

lis by Gardner and Dukes (1955) because it was a Gram-negative or Gram-variable, rod-shaped bacterium isolated successfully on blood agar medium but not on other agar media. Furthermore, it was considered the etiologic agent of bacterial vaginosis, even if its role in this pathology was controversial, because no appropriate methods of detection and identification for this fastidious organism were available. Today it has been recognized that bacterial vaginosis is also associated with other microorganisms such as *Bacteroides* spp., *Mobiluncus* spp., *Mycoplasma hominis*, *Peptostreptococcus* spp., etc. Zinmann and Turner (1963) suggested the removal of *Haemophilus vaginalis* from the genus *Haemophilus* and its reclassification in the genus *Corynebacterium* as *Corynebacterium vaginalis*; this statement was based on the similarity of Gram stain reaction and cellular morphology to the member of this genus and on the absence of requirements for X and V factors (hemin and NAD, respectively) which are needed for the growth of *Haemophilus* species. In the first study of *Haemophilus vaginalis* by electron microscopy, Reyn et al. (1966) showed that the fine structure of its cell wall resembled that of a Gram-positive bacterium, and it could be placed in the genus *Corynebacterium* or *Butyrivacterium*. These authors also indicated that this bacterium may be closely related to the genus *Propionibacterium*. Differently from Reyn et al. (1966), Criswell et al. (Crisweel et al., 1971; Crisweel et al., 1972) in their study concluded that the fine structure examined by electron microscopy and the biochemical composition of the cell walls of *Haemophilus vaginalis* were typical of a Gram-negative bacterium. Moss and Dunkelberg (1969), based on a study on the volatile acid production, showed that *Haemophilus vaginalis* should be placed neither in the genus *Corynebacterium* or *Butyrivacterium* nor in the genus *Lactobacillus* (as was suggested by Buchanan and Gibbons, 1974), because the main fermentation product is acetic acid rather than lactic, butyric or propionic acid.

In 1980, Greenwood and Pickett described the new genus *Gardnerella* with the species *Gardnerella vaginalis* in the absence of existing genera with genetic features compatible with those of *Haemophilus vaginalis* (Greenwood and Pickett, 1980). Piot et al. (1980) in the same year came to the same conclusion. In the 1986 edition of *Bergey's Manual of Systematic Bacteriology* (Sneath et al., 1986), *G. vaginalis* has been included in the group of facultatively anaerobic Gram-negative rods. In agreement with Sadhu et al. (1989), a recent study of cell-wall ultrastructure of *G. vaginalis* type strain confirms the Gram-positive nature of its cell wall (Muli et al., 1999); this report stated that any Gram variabil-

ity staining can be ascribed to variations in the thickness of the cell wall, as was pointed out before.

The phylogenetic study based on 16S RNA homology clarified the taxonomic position of genus *Gardnerella* which, together with genus *Bifidobacterium*, has been included in the family of Bifidobacteriaceae (Stackebrandt et al., 1997). *Gardnerella vaginalis*, besides the phylogenetic affinity, shares the presence of the key enzyme fructose-6-phosphate phosphoketolase in common with bifidobacteria (Gavini et al., 1996).

Milestones in the *Gardnerella* taxonomy are reported in Fig. 23.

Habitat

Gardnerella vaginalis is commonly isolated from female genital tract and can occur as an endogenous organism of the vaginal flora in a population of healthy women. Overgrowth of *G. vaginalis*, which is present normally in low number, is involved in bacterial vaginosis. *Gardnerella vaginalis* transiently colonizes the genital tracts of healthy males as a result of continued passive acquisition from their female partners (Holst, 1990) or this microorganism may have been part of bacterial flora propria of these subjects, as suggested by Smith et al. (1992). In males, *G. vaginalis* can be involved in genital and urinary tract infections (Smith et al., 1992).

Gardnerella vaginalis can be found also in the anorectal flora of both sexes as well as children (Holst, 1990). In addition, *Gardnerella vaginalis* has been isolated from the reproductive tract of mares; probably they are normal inhabitants of the equine genital tract (Salmon et al., 1991).

Isolation

SPECIMEN COLLECTION, TRANSPORT AND STORAGE
Material for the culture of *G. vaginalis* is obtained by swabbing the vaginal introitus with a cotton-tipped swab. It is preferable to take two swabs: one for immediate examination and the other for culturing, such as is necessary for epidemiological studies. If the culture media cannot be directly inoculated, then the swab should be placed in a transport medium and culture should be done within 24 h (Funke and Bernard, 1999). It is noteworthy that *G. vaginalis* is susceptible to sodium polyanethole-sulfonate (SPS), so an SPS-free medium (or an SPS medium supplemented with gelatin, which overcomes the inhibitory effect of SPS) should be used to achieve optimal recovery of *G. vaginalis* from a blood culture system (Reimer and Reller, 1985a).

NONSELECTIVE MEDIA Nonselective or differential media for the detection of small numbers of *G. vaginalis* organisms, among other commensal microorganisms frequently found in the genital tract, support fairly well the growth of *G. vaginalis*. None of these media inhibit lactobacilli and other common vaginal Gram-positive bacteria such as coryneforms and streptococci. Casman agar (Leopold, 1953), chocolate agar (Pheifer et al., 1978), GC agar (Difco), and peptone-starch-dextrose agar (Dunkelberg et al., 1970) have been frequently used to grow *G. vaginalis*.

Chocolate Agar This medium contains GC agar base (BBL), 1% ISOVITALEX enrichment (BBL) and heated "chocolatized" 5% sheep blood. *Gardnerella vaginalis* is identified as pinpoint colonies appearing after 48 or 72 h; they produce no surrounding green discoloration of the agar reference medium (Pheifer et al., 1978).

Peptone-Starch-Dextrose Agar (PSD) This medium contains 2% proteose peptone No. 3 (Difco), 1% soluble starch, 0.2% dextrose, 0.1% $\text{Na}_2\text{HPO}_4 \cdot \text{H}_2\text{O}$ and 1.5% agar (Dunkelberg et al., 1970).

Dunkelberg and McVeigh (1969) have observed that only two commercial peptones (Difco proteose peptone no. 3 and possibly BBL myosate) of all the peptones tested contain the required growth factors for *G. vaginalis*. Smith (1975) modified PSD by adding a pH indicator to the medium, allowing the detection of *G. vaginalis* by the production of acid from starch around the colonies. The addition of 0.2% (final concentration) Tween 80 to PSD medium enhances the growth of the majority of strains of *G. vaginalis*, perhaps because it may compensate for some nutritional deficiency in the basal peptone used in the pre-reduced medium (Malone et al., 1975).

The use of nonselective media permits the relative quantification of *G. vaginalis* growth, whereas media designed to yield a higher isolation rate of *G. vaginalis* fail to indicate the relative numbers of this organism in mixed genital flora. With nonselective media, a higher degree of correlation has been observed between clinical symptoms and specimens yielding a pure growth of *G. vaginalis* than between clinical symptoms and specimens yielding predominant, mixed, or light growths (Ratnam and Fitzgerald, 1983).

Selective Media

Media for selective growth of *G. vaginalis* have been developed. β -Hemolysis observed in human or rabbit (not sheep) blood-containing media allows β -hemolytic *G. vaginalis* to be dis-

tinguished from among numerous nonhemolytic colonies. *Gardnerella vaginalis* is resistant to several antibiotics including amphotericin, colistin, nalidixic acid and gentamicin, which can be incorporated into selective media (Taylor-Robinson, 1984). Anaerobic or facultatively anaerobic Gram-negative vaginal flora are inhibited by colistin and nalidixic acid, and yeasts are inhibited by amphotericin B (Piot and Van Dick, 1983).

The organism grows best at 35–37°C in a 5–7% CO_2 atmosphere. Plates may be checked for the growth of diffuse β -hemolytic colonies of <0.5 mm in diameter after 24 h, but very often *G. vaginalis* is better observed after 48 or 72 h. Gram-staining of the suspected colonies confirms the diagnosis of *G. vaginalis*. The performance of confirmatory tests usually requires subculturing and incubation for another 24–48 h.

HUMAN BLOOD BILAYER TWEEN (HBT) AGAR

The ability to detect *G. vaginalis* has improved with the development in 1982 of an HBT medium by Totten et al. (1982). It was composed of a basal layer of 7 ml of CNA agar (Columbia agar base containing colistin and nalidixic acid, BBL Microbiology Systems), 1% proteose peptone no. 3 (Difco), and 0.0075% Tween 80 with amphotericin B (2 $\mu\text{g}/\text{ml}$) and of a 14-ml overlay of the same composition plus 5% human blood. Tween 80, amphotericin B and human blood were added after autoclaving. Tween 80 improves hemolysis and enhances growth. Colonies of *G. vaginalis* are identified as small white colonies that produce β -hemolysis after 48–72 h of incubation in 5% CO_2 (Totten et al., 1982). Because zones are viewed through a shallower layer of blood-containing medium, hemolysis is easier to detect on a double-layer as opposed to a single-layer HBT medium. Significantly, *G. vaginalis* was isolated from vaginal fluids more often on HBT than on Vaginalis agar ($P=0.007$; Totten et al., 1982). Holst (1990) used HBT with good results to isolate *G. vaginalis* from anorectal samples. This medium is the most satisfactory selective medium at present, even if it fails to inhibit a variety of Gram-positive bacteria such as lactobacilli, coryneforms and streptococci of the endogenous and bacterial vaginosis-associated flora (Piot and Van Dick, 1983; Spiegel, 1991). Isolates of Gram-positive or Gram-variable pleomorphic rods that showed β -hemolysis in this medium were identified as *G. vaginalis* if they produced acid from starch and maltose and were negative for catalase and oxidase (Spiegel et al., 1980). *Gardnerella vaginalis* when grown anaerobically on HBT medium with some other anaerobic constituents is also β -hemolytic. The addition to the HBT medium of gentamicin (4 mg/liter) instead of colistin

increases the inhibition towards non-*Gardnerella* species (Ison et al., 1982).

COLISTIN AND NALIDIXIC ACID MEDIUM (CNA) This is a semiselective medium containing colistin (10 µg/ml) and nalidixic acid (15 µg/ml) incorporated in a Columbia agar base (Goldberg and Washington, 1976). The addition of 1% cornstarch allows the discrimination of *G. vaginalis* colonies by their hydrolytic clearing of the opaque agar (Mickelsen et al., 1977).

VAGINALIS (V) AGAR This medium is an enriched and selective medium. It contains GC agar; the addition of 2% hemoglobin and 5% fetal bovine serum enhances the recovery of the microorganism. Vancomycin at 3 µg/ml is added to the medium to inhibit contaminating bacteria (Chapin and Murray, 1999).

COLISTIN-OXOLINIC ACID BLOOD AGAR (COBA-10) Columbia agar base contains 5% defibrinated sheep blood, 10 mg of sodium colistimethate per liter and 10 mg of oxolinic acid per liter (Thompson, 1985). This selective medium is useful for isolating *G. vaginalis* from vaginal and cervical specimens. However, COBA-10 grew lactobacilli, yeast, hemolytic streptococci, and viridans group streptococci equally well, whereas other vaginal diphtheroids and some enterococci were inhibited by COBA-10. Incubation occurs at a temperature of 37°C for 48 h in a humidified atmosphere of air plus 5–10% CO₂.

Commercial blood culture media, routinely with the anticoagulant SPS added, are inhibitory for *G. vaginalis* (Reimer and Reller, 1984). The adverse effect of SPS is overcome by the addition of gelatin to SPS-containing media (Reimer and Reller, 1985a). Failure to detect bacteremia where *G. vaginalis* is present may be due to SPS inhibition (Gibbs et al., 1987; Lee et al., 1987).

SORBAROD BIOFILM MEDIA Sorbarod biofilm media to investigate the growth characteristics of *G. vaginalis* and *Lactobacillus acidophilus* separately or together have been developed. This system is labor intensive but it appears suitable for studying the interaction of bacteria in biofilms (Muli and Struthers, 1998).

Identification

Clinical Diagnosis of Bacterial Vaginosis

The isolation of *G. vaginalis*, although not recommended for routine laboratory procedures, can support the diagnosis of bacterial vaginosis. In fact massive growth of *G. vaginalis* (about

10⁸ CFUs/ml of vaginal fluid) in the absence or with a low number of lactobacilli is a better predictor of bacterial vaginosis than predominant, mixed or light growth. In clinical diagnosis, the “gold standard” for identification of bacterial vaginosis is the direct examination of vaginal secretions based on these parameters:

- 1) an abnormal vaginal discharge;
- 2) the presence of clue cells (vaginal epithelial cells whose peripheral borders are obscured because they are covered with adherent bacteria) on a wet mount of a smear examined microscopically; *G. vaginalis* has been shown to be the dominant organism adherent to exfoliated clue cells (Cook et al., 1989). The Gram-staining of the same microscopy preparation can give another indication of the presence of short Gram-negative or Gram-variable bacilli corresponding to *G. vaginalis* (Ison et al., 1982); normally *G. vaginalis*, besides having a Gram-positive type of organization because of the unusual thinness of the cell walls, tends to display Gram-negative or Gram-variable reaction (Sadhu et al., 1989);
- 3) a positive amine test performed by mixing a drop of 10% KOH solution with the discharge (milky homogenous vaginal discharge). The release of an amine (fishy) odor is a positive test. In bacterial vaginosis, the combination of *G. vaginalis* and other anaerobes actually produces organic acids (other than lactic acid) as well as several amines (Chen et al., 1979). These amines, in the presence of an elevated vaginal pH, readily volatilize to produce putrescine, cadaverine, methylamine, etc., which are the substances primarily responsible for the fishy odor in bacterial vaginosis. *Gardnerella vaginalis* itself is not thought to produce the polyamine but may elaborate catabolic products that facilitate the growth of anaerobes (such as *Mobilunculus*, which for example produces trimethylamine in bacterial vaginosis; Cruden and Galask, 1988).

A new diamine test for a rapid diagnosis of bacterial vaginosis was described by O'Dowd et al. (1996). Additional information can be obtained by examining the vaginal pH, which is greater than 4.5 in bacterial vaginosis. These diagnostic criteria cannot be readily applied to prepubertal children because the immature vagina is an alkaline environment. Also, the absence of *Trichomonas vaginalis* is an additional predictor for bacterial vaginosis diagnosis.

Additional tests currently commercially available use the detection of bacterial by-products (e.g., PIP, proline endopeptidase, an enzyme frequently found in vaginal secretions of women with bacterial vaginosis), elevated pH and amine, or oligonucleotide probes for *Gardnerella* (Schwebke, 1999; Sheiness et al., 1992). Furthermore, PCR 16S RNA gene methods have been

set up for the identification of *G. vaginalis* (Nath et al., 2000).

Tests for the Identification of *G. vaginalis*

The predictive value of the growth of *G. vaginalis* in the diagnosis of bacterial vaginosis was only 49%, but a negative culture for *G. vaginalis* practically excluded bacterial vaginosis (Piot and Van Dick, 1983). It is unclear whether women who carry *G. vaginalis* in the vagina ultimately develop bacterial vaginosis and why some women carrying *G. vaginalis* have bacterial vaginosis and others do not.

The presence of positive results using the diagnostic criteria might prove to be particularly suitable in the first-contact clinic and could rule out the need for identification of *G. vaginalis*. The incidental finding of *G. vaginalis* from a routine vaginal culture should not be used to diagnose bacterial vaginosis because many women with *G. vaginalis* organisms show no signs of bacterial vaginosis. The identification of *G. vaginalis* is important also in the study of urinary tract infections in men because urinary tract infections caused by this microorganism have also been described (Smith et al., 1992).

The major problem in the diagnostic laboratory is the differentiation of *G. vaginalis* from other catalase-negative coryneform or diphtheroid coccobacilli, which occur commonly in vaginal specimens. For the identification of *G. vaginalis*, it is possible to use some confirmatory tests which, on the other hand, may not always be required by experienced microbiology technologists, considering they can usually identify the organism by colony morphology and Gram stain appearance (Reimer and Reller, 1985a).

Bailey et al. (1979) explored the possibility of using API 20A (Analylab Products Inc., Plainview, N.Y.), Minitek, and the rapid buffered-substrate fermentation (RTF) systems (Brown, 1974) and compared them to conventional tests. Results confirmed by Greenwood et al. (1977) showed API and Minitek gave variable and unreliable results, although RTF gave results comparable with conventional tests.

The following protocols are more frequently applied for identification:

CELLULAR MORPHOLOGY AND GRAM-STAINING *Gardnerella vaginalis* cells (Fig. 24) are generally small, pleomorphic rods that are nonmotile, nonsporeforming and do not possess flagella, endospores or typical capsules (Greenwood and Pickett, 1980). Cellular morphology varies with the medium on which the organism was grown. Bacilli from chocolate agar are slightly larger and more pleomorphic than those from Schlaedler agar (Oxoid) or Bacto-peptone agar.

Fig. 24. Cellular morphology of *G. vaginalis*. ATCC 14018^T.

In these latter media, the morphology resembles the control organism (NCTC 10287) in being predominantly coccobacillary (Jolly, 1983). The Gram stain varies considerably depending on the medium and the age of the culture. Consequently cellular morphology and size are more helpful than the Gram reaction itself. Structurally, it is a Gram-positive microorganism, but it has an unusual cell-wall structure that does not retain Gram's stain and generally appears as Gram-variable or Gram-negative (Sadhu et al., 1989).

RAPID IDENTIFICATION SYSTEM This system is known as the rapid-strip bacterial identification system, the API 20A (Analylab Products Inc., Plainview, N.Y.), Rapid ID32 Strep, and the API Coryne galleries (bioMérieux, La Balme les Grottes Montalieu-Vercieu, France). According to Taylor and Phillips (1983), many of the performance results differed quite considerably from those of Piot et al. (1980) and so this system of enzyme detection should not be used for the definitive identification of *G. vaginalis*.

PRESENCE OF CATALASE AND OXIDASE Growth from a 48-h chocolate agar plate is placed on a glass slide using a wooden applicator stick, overlaid with a drop of 3% H₂O₂ and then observed for evolution of bubbles. For the oxidase test, growth is smeared with a platinum loop on a filter paper strip saturated with a solution of 1% (w/v) tetramethyl-*p*-phenylenediamine dihydrochloride in 0.2% (w/v) ascorbic acid (Greenwood and Pickett, 1979). The results of both tests are negative for *Gardnerella vaginalis*.

HYDROLYSIS OF HIPPURATE *N*-Benzoylglycine (hippurate) hydrolysis is performed according to Hwang and Ederer (1975). A stock solution of 1% sodium hippurate is dispensed in 0.4-ml aliquots into test tubes. A loopful of the test organism from the overnight growth plate is emulsified

in the hippurate solution and incubated for 2 h at 37°C. Then 0.2 ml of ninhydrin solution is added and re-incubated for 10 min. A positive reaction is indicated by the development of a purple color. The optimal pH of the substrate solution giving no false-negative or false-positive reactions is 6.4. Shaking of the test solution occasionally produces false-positive reactions (Piot et al., 1982). This test was less specific in respect to an SPS-disk test or an α -hemolytic (α -strep) test. Reimer and Reller (1985a) obtained a positive reaction in 50 out of 62 strains of *G. vaginalis* tested; also Piot et al. (1982) observed that 58% of unclassified coryneforms hydrolyzed hippurate. Although Reimer and Reller (1985a) do not consider this to be an important screening test, Jolly (1983) considers it fundamental to an accurate identification of *G. vaginalis*. As this test is not positive in 100% of the tested strains, it is only partially useful for the identification of *G. vaginalis*.

Susceptibility to Metronidazole and Sodium Polyanetholesulfonate A useful characteristic for the identification of *G. vaginalis* is the presence of a zone of inhibition around the disks containing 50 μ g of metronidazole (Totten et al., 1982) or 1 mg of sodium polyanetholesulfonate (SPS; Reimer and Reller, 1985b). According to Jones (1985), the SPS test helps to exclude catalase-positive vaginal coryneforms and lactobacilli, but does not differentiate true *G. vaginalis* from the atypical, catalase-negative “*G. vaginalis*-like” organisms from the vagina; this inability remains the major problem in vaginal bacteriology.

HEMOLYSIS, COLONIAL AND CELL MORPHOLOGY ON HBT MEDIUM A presumptive identification in the clinical laboratory can be carried out using the culture of vaginal swabs on HBT medium and by the observation of the colonial morphology, clear β -hemolysis with a diffuse edge on HBT agar, negative catalase production, and typical cellular morphology in the Gram stain. All *G. vaginalis* strains as well as about 50% of catalase-negative coryneforms are β -hemolytic. However, hemolysis by catalase-negative coryneforms strains is nearly always weaker and the zone is of smaller diameter than that of *Gardnerella*-type hemolysis. Catalase-negative coryneforms generally yield smaller colonies and are more often pleomorphic, fairly thick and predominantly Gram-positive rods. *Gardnerella vaginalis* cells are rather thin, Gram-negative or Gram-variable, short rods. The quality of the hemolysis is, however, dependent on the age of the blood, which should just have time-expired (Ison et al., 1982). The diffuse β -hemolysis produced by *G. vaginalis* on human (but not on horse) blood

agar has proven very useful in differentiating it from other vaginal organisms and is not affected by the antibiotic added to the substrate (Ison et al., 1982).

LIPASE ACTIVITY Lipase activity was shown by the oily, iridescent sheen on an enriched egg yolk medium after anaerobic incubation. The plates were examined each day for 5 days to detect lipase (Holdeman et al., 1977). A more recent lipase test method uses an oleate substrate (Briselden and Hillier, 1990). The lipase reaction when present is helpful in detecting *G. vaginalis*, particularly in mixed cultures. Unfortunately, not all strains uniformly give this reaction (Greenwood and Pickett, 1979). This test is used in the determination of *G. vaginalis* biotypes (Briselden and Hillier, 1990).

CARBOHYDRATE FERMENTATION Fermentation of maltose, dextrose and fructose, in addition to starch, has been considered in many identification procedures (Shaw et al., 1981; Piot et al., 1982; Taylor and Phillips, 1983). Dunkelberg et al. (1970), however, have suggested that it is superfluous to test for dextrose and maltose fermentation because an organism which can acidify starch can likely acidify dextrose and maltose also.

INHIBITION BY α -HEMOLYTIC STREPTOCOCCUS The α -hemolytic streptococcus (α -strep) test is performed by inoculating a 0.5 McFarland standard suspension on a chocolate agar. A streak with *Streptococcus sanguis* ATCC 35557 is then made across the center of the plate, and the plate is incubated for 24–48 h at 37°C in 5% CO₂. A positive test requires inhibition of growth along the streptococcal streak. Preliminary tests showed that the test was less reliable with media other than chocolate, when incubated under anaerobic conditions, or using other strains of streptococci (Reimer and Reller, 1985b).

FATTY ACID COMPOSITION The fatty acid composition is characteristic and relatively simple. The differences among isolates are insignificant. *Gardnerella vaginalis* possesses polar lipids and fatty acids (i.e., linear chain saturated and unsaturated non-hydroxylated fatty acids: hexadecanoic acid [16:0], octadecenoic acid [18:1], and octadecanoic acid [18:1]). Polar lipids are mostly characterized by the presence of diphosphatidylglycerol, phosphatidylglycerol or phosphatidylinositol (Csango et al., 1982; Van Esbroeck et al., 1996).

FRUCTOSE-6-PHOSPHATE PHOSPHOKETOLASE TEST Fructose-6-phosphate phosphoketolase (F-6-

PPK) is present in all bifidobacterial species (Biavati et al., 1991) and in *G. vaginalis* as well (Gavini et al., 1996), but the two genera can be easily distinguished on another basis. For the procedure of F-6-PPK test, see identification section of *Bifidobacterium* genus.

The above tests are useful for the identification of *G. vaginalis* but usually confirmatory tests have to be obtained by a combination of tests: a limited number of biochemical reactions could fail to give a definitive identification. The most valuable characteristics are the presence of α -glucosidase, the absence of β -glucosidase, the hydrolysis of starch and hippurate, and the hemolysis of human but not sheep blood (Catlin, 1992; Reimer and Reller, 1985b).

Preservation of Cultures

Short-term Methods

A Casmaan's medium base (Difco cat. number 0290) with 5% rabbit blood is used for preservation of strains of *G. vaginalis* in liquid media. The cultures are transferred every week and are incubated in an atmosphere containing a 5% CO₂-enriched atmosphere.

Long-term Methods

Longer maintenance can be achieved by freezing below 130°C (deep freezer), of liquid nitrogen or by freeze-drying. The following cryoprotective agent may be used: skim milk solution (10% skim milk, 3% lactose and 3% yeast extract; the solution, after shaking for 20 min, is autoclaved at 110°C for 30 min). For details and other methods, see Gherna (1994).

Physiology

The most important physiological characteristics of *G. vaginalis* are shown in Table 7.

Temperature Requirements

Optimum growth occurs at temperatures between 35 and 37°C; however, growth can occur between 25 and 45°C (Greenwood and Pickett, 1979).

pH Requirements

Optimum growth occurs at a pH between 6 and 6.5; no growth occurs at pH 4 and slight growth occurs at pH 4.5 and pH 8.0 (Greenwood and Pickett, 1979; Buchanan and Gibbons, 1974).

Anaerobiosis

Gardnerella vaginalis has a fermentative metabolism with acetic acid as the major end product (Moss and Dunkelberg, 1969). It is facultatively anaerobic and uses carbohydrates as its major energy source (Greenwood and Pickett, 1980). It grows well in microaerophilic conditions in a 5–7% CO₂ atmosphere. Malone et al. (1975) described six strains that were strictly anaerobic on original isolation. One strain, however, when re-tested after lyophilization grew on the surface of plates incubated in a 5–7% CO₂ atmosphere. Piot and Van Dick (1983) also isolated four of 145 vaginal isolates after incubation in anaerobic conditions, of which two failed to grow in microaerophilic conditions after 10 subcultures. Anaerobic strains of *G. vaginalis* seem to be rare, and routine anaerobic incubation is not recommended (Piot and Van Dick, 1983). There were no differences among the characteristics of anaerobic and facultatively anaerobic strains, except for the occurrence of mannose fermentation (very weak in anaerobic strains). Today, it is more practical to use a commercially available kit to grow *G. vaginalis* in microaerophilic conditions.

Enzymes

Gardnerella vaginalis has a variable biochemical lipase and β -galactosidase profile. It possesses esterase (C4), esterase lipase, and α -glucosidase, but does not possess β -glucosidase (Greenwood and Pickett, 1979; Piot et al., 1982).

Carbohydrate Fermentation

Carbohydrate reactions were very variable owing to differences in the methodology used. Dextrose fermentation, for example, was reported to be positive for 100% of 63 strains tested with buffered single substrates (Greenwood et al., 1977), whereas only two of 16 were positive for cystine-trypticase agar (Smith, 1975). Similar variability has been reported for sucrose (Dunkelberg et al., 1970). The results of fermentation of other carbohydrates are reported in Table 8.

Toxin Production

A cytolytic extracellular toxin released by *G. vaginalis* during growth in a supplemented peptone broth containing starch and Tween 80 was described by Rottini et al. (1990). This hemolysin was specific for human erythrocytes and had no activity on horse, rabbit, sheep or guinea pig erythrocytes. This toxin can produce lysis of human polymorphonuclear leukocytes and human endothelial cells. This cytolytic toxin forms a voltage-dependent cationic channel when incorporated into lipid membranes (Moran et al., 1992).

Phospholipase A₂ Activity

Gardnerella vaginalis was identified as a member of the vaginal flora having phospholipase A₂ activity, which initiates labor (Bejar et al., 1981).

Nutrition

Gardnerella vaginalis is a fastidious microorganism, but does not require either hemin or NAD (X and V factors, respectively) for growth. A semi-defined liquid medium that permits the growth of two *G. vaginalis* strains, 594^T (ATCC 14018) and 317 (ATCC 14019), was developed (Dunkelberg and McVeigh, 1969). Interestingly, the strain 594 required adenine for growth, whereas the strain 317 did not. Neither strain grew in the absence of purine and pyrimidine bases. The omission of any one of the six bases (except adenine) from the medium did not reduce growth.

Iron plays an important role in the virulence potential of many bacterial pathogens (Griffiths, 1991). The ability of different strains of *G. vaginalis* to acquire iron from the medium was studied by Jarosik et al. (1998). The authors found that all strains examined were able to acquire iron from ferric and ferrous inorganic substrates as well as from hemin, catalase, hemoglobin, lactoferrin but not transferrin. In *G. vaginalis*, several proteins were recognized to be iron-regulated.

It would be useful to study the nutritional requirements of *G. vaginalis* strains because of the scarcity of such data in the literature.

Antimicrobial Susceptibility

Ninety percent of the strains of *G. vaginalis* are susceptible to penicillin (0.07 mg/liter), ampicillin (0.125 mg/liter), vancomycin (0.5 mg/liter), clindamycin (<0.06 mg/liter), gentamycin (4 mg/liter) and amphotericin B (2 mg/liter). *Gardnerella vaginalis* is susceptible to metronidazole (4mg/liter) and its hydroxy metabolite (1 mg/

liter), which is one of the main metabolites of metronidazole produced in vivo (McCarthy et al., 1979; Bannatyne et al., 1987). It is resistant to cephalixin (64 mg/liter), tetracycline (64 mg/liter), nalidixic acid (>128 mg/liter), colistin (>128 mg/liter), sulfadiazine (>128 mg/liter), and quinolones (>4 mg/liter; Jones et al., 1982; Tjiam et al., 1986; Ison et al., 1982). The minimal inhibitory concentration (MIC) of tetracycline showed a bimodal distribution (Kharsany et al., 1993; McCarthy et al., 1979); high-level resistance (>64 mg/liter) has been attributed to the Tet(M) conjugative transposon located on the chromosome (Roberts and Hillier, 1990; Huang et al., 1997).

It is insensitive to sulfonamides and resistant to trimethoprim. Metronidazole is the most efficacious drug for the treatment of bacterial vaginosis related to the presence of *G. vaginalis*. Evidence that bacterial vaginosis is susceptible to treatment with metronidazole (a drug active against anaerobic bacteria) supports the hypothesis that bacterial vaginosis is due to a set of anaerobic bacteria that are sustained by the presence of *G. vaginalis*. Ampicillin can be used just for the treatment of a *G. vaginalis* infection, such as a urinary tract infection or a postpartum sepsis. Nevertheless, ampicillin treatment failed to eradicate bacterial vaginosis where *G. vaginalis* was present with species of anaerobes. These other anaerobes presumably inactivate the drug via β -lactamase inhibition. Augmentin, in which clavulanic acid protects the β -lactam ring of amoxicillin from enzymatic cleavage, was used successfully for the treatment of bacterial vaginosis (Symonds and Biswas, 1986).

Ultrastructure

Electron microscopy studies have produced two opinions, one confirming that *G. vaginalis* is Gram positive (Reyn et al., 1966; Sadhu et al., 1989) and another stating that *G. vaginalis* is Gram negative, the latter based on both electron microscopic and biochemical evidence (Crisweel et al., 1971; Boustouller et al., 1987). The recent electron microscopy study of Muli et al. (1999) on the cell wall of *G. vaginalis* grown on conventional medium and in biofilm systems confirms the Gram-positive nature of the cell wall. The Gram variability can be ascribed to variations in the thickness of the cell wall as observed by Sadhu et al. (1989).

Furthermore, *G. vaginalis* cell walls do not contain the classical lipopolysaccharides found in Gram-negative organisms and contain major amounts of alanine, glutamic acid, glycine and lysine; glucose, galactose and 6-deoxytalose, a diagnostic sugar, are also found (Harper and Davis, 1982).

Exopolysaccharides and Pili

The microcapsular material that is visible in electron microscope preparations has been demonstrated to be a flocculent or fibrillar external polysaccharidic layer named "exopolysaccharide" (Scott et al., 1989; Greenwood and Pickett, 1980; Sadhu et al., 1989; Crisweel et al., 1972). It possesses a role in the adhesive nature of *G. vaginalis* and accounts in part for the clustering of cells in culture.

Gardnerella vaginalis possesses pili with a diameter ranging from 3 to 7.5 nm. The presence of pili is more frequent in clinically isolated than laboratory cultured strains (Boustouller et al., 1987; Johnson and Davies, 1984).

Genetics

Few studies on *G. vaginalis* are present. Nath et al. (1992) demonstrated that *G. vaginalis* in bacterial vaginosis represents a genetically mixed population; this conclusion was drawn using restriction endonuclease analysis (REA) and restriction fragment length polymorphism (RFLP) as well as by biochemical studies (bio-typing based on β -galactosidase, lipase and hippurate hydrolysis; Briselden and Hillier, 1990). Nath et al. (1991) used a nonradioactive probe derived from a 5.7-kb DNA fragment from *G. vaginalis* ATCC 14018 to perform RFLP on 12 *G. vaginalis* strains and demonstrated the usefulness of this detection method for the study of this organism.

Similarly, Pao et al. (1990) used a DNA cloned from digested genomic potentially *G. vaginalis* DNA to serve as a probe and described this probe as having no crossreactions with a number of non-*Gardnerella* microorganisms.

Van Belkum et al. (1995) developed a species-specific PCR assay for the determination of *G. vaginalis* using the internal transcribed spacer (ITS) region of *G. vaginalis* DNA (between the 16S and 23S RNA genes) and the 23S rRNA gene. This PCR analysis in 10% of women, irrespective of their clinical status, detected *G. vaginalis*, whereas 10 out of the 11 patients with bacterial vaginosis were carrying *G. vaginalis*. Nath and Galdi (1995) refined the procedure to isolate *G. vaginalis* DNA from cultures by reducing the total extraction time and using an NaCl salting-in/out procedure to remove proteinaceous material.

Wu et al. (1996) analyzed 20 biotype "1" *G. vaginalis* strains, 10 from patients with bacterial vaginosis and 10 from patients without bacterial vaginosis. None had the same DNA fingerprint pattern. However, irrespective of the clinical status, 18 of the 20 samples were positive for a 1.18-kb Hind III fragment using RFLP.

Ecology

The composition of the endogenous vaginal flora is influenced by interactions (although not yet completely understood) among the host, the bacteria and exogenous factors. For example, estrogen produced by adult females increases glycogen in the vaginal epithelium, which is fermented by lactobacilli. Through this fermentation, lactobacilli produce acid and fulfill a central role in vaginal homeostasis of protecting the urogenital tract from pathogenic infections (Eschenbach, 1993). Before puberty, the female vagina is basic and does not produce glycogen. After menopause, glycogen disappears and the pH and the flora resemble their prepubertal status. In this stage of life, lactobacilli are absent and the vaginal flora consist mostly of staphylococci, diphtheroides and *E. coli*. In clinically healthy women also, some investigators have described the presence of *Bifidobacterium* species, such as *B. breve*, *B. adolescentis*, *B. longum* and *B. bifidum* (Crociani et al., 1973; Korschunov et al., 1999). The role played by bifidobacteria has not been elucidated; it is possible, however, bifidobacteria similar to lactobacilli are able to produce inhibitory substances such as organic acids and bacteriocins that inhibit different pathogens. The factors that initiate the shift in the ecology of the vagina, in which there is overgrowth of organisms already present or newly introduced, are incompletely understood. These changes in microbial flora with a prevalence of microorganisms such as *G. vaginalis*, *Mycoplasma* spp., anaerobic Gram-negative rods (*Prevotella* spp.), *Peptostreptococcus* spp., *Ureaplasma urealyticum*, and often *Mobilunculus* spp. (Hill, 1993) result in nonspecific vaginitis also named "bacterial vaginosis." Much remains to be learned about the interactions among members of the vaginal flora. Skarin and Sylwan (1986) found that vaginal microflora of *Lactobacillus acidophilus* and *L. casei* can inhibit growth of *G. vaginalis* and species of *Mobiluncus*, *Bacteroides* and anaerobic cocci on solid media by producing acid. Another possible antibacterial agent is hydrogen peroxide. Interestingly H_2O_2 -producing lactobacilli are predominant in healthy women. *Lactobacillus* species which do not produce hydrogen peroxide are present in 36% of women with bacterial vaginosis (Eschenbach et al., 1989).

Gardnerella vaginalis may occasionally ascend to the upper genital tract of females and it has been isolated from cases of endometritis and salpingitis (Watts et al., 1989). *Gardnerella vaginalis* also has been isolated from wound infections and blood specimens (Sturm et al., 1983; Reimer and Reller, 1984; Holst, 1990). The reservoir of *G. vaginalis* and other microorganisms

such as *Mobilunculus* and *Mycoplasma hominis* involved in bacterial vaginosis is also in the intestinal tract. They may be isolated from the rectums of women, men and children. The occurrence of these microorganisms is higher in the rectums of women who develop bacterial vaginosis compared to that found in the rectums of healthy subjects. The data regarding microbial composition of urethral samples from male sexual partners of women with bacterial vaginosis do not support the notion of a sexual transmission of bacteria associated with this pathology, even though men can acquire *G. vaginalis* through sexual contact (Holst, 1990; Bump and Buesching, 1988).

Gardnerella vaginalis has been isolated from the reproductive tract of mares as well. It is not known whether these microorganisms contributed to the reproductive problems of mares, inasmuch as *G. vaginalis* has been isolated in very small numbers, usually along with other microorganisms. Their role as pathogens is unclear; probably they are common inhabitants of the equine genital tract (Salmon et al., 1991).

Epidemiology

Bacterial vaginosis is associated with serious upper genital tract infections and an adverse pregnancy outcome (Sweet, 1995). In particular, the presence of bacterial vaginosis in pregnant women increases the risk of preterm delivery and there is now compelling evidence that bacterial vaginosis is a cause of preterm delivery (Hillier et al., 1995). In addition, the composition of the vaginal microflora has a significant impact on the overall health of women (Hill et al., 1984), and the abnormal and often foul-smelling discharge that accompanies bacterial vaginosis is of great concern to many women. These considerations combined with the high frequency of occurrence prompt the necessity for a greater understanding of the pathogenesis of bacterial vaginosis.

Gardnerella vaginalis was found to be present in 30–50% of normal women without evidence of bacterial vaginosis. Differences in the literature on the percentage of healthy women infected by *G. vaginalis* arise mainly from the different methodologies applied. However, using selective media, a high prevalence of *G. vaginalis* was documented in patients with bacterial vaginosis (98–100%).

Nevertheless, epidemiological studies of bacterial vaginosis suffer from a lack of clinical microbiological precision. Data from several studies propose that the prevalence varies from 15% in private gynecological patients (Bump et al., 1984) to 10–30% in pregnant women

(Gardner et al., 1957; Hill et al., 1983; Minkoff et al., 1984), whereas it was found to be 5–25% in college students (Spiegel et al., 1980; Eschenbach et al., 1988). Its prevalence range in other populations is extremely broad.

The definition of risk factors for bacterial vaginosis varies significantly, but two factors seem to be important: non-white race and the use of intrauterine devices. The effects of previous pregnancy or sexual activity are inconsistent from study to study, but it is clear that bacterial vaginosis is not exclusively a sexually transmitted disease. *Gardnerella vaginalis* has been isolated from urine samples in men with a clinical incidence of 0.1%; *G. vaginalis* may play a role in causing urinary tract infection in at least 67% of males patients from whom it was isolated (Smith et al., 1992).

Biotyping schemes based on the presence of lipase, hippurate hydrolysis and β -galactosidase have identified specific biotypes associated with bacterial vaginosis. The urethra of men and their partners who had bacterial vaginosis were colonized with the same biotype of *G. vaginalis* when the partners are cultured within 24 h of each other. The distribution of biotypes was the same in women with and without bacterial vaginosis. The treatment regimen used, and not the presence of a new sexual partner, was associated with the acquisition of a new biotype (Briselden and Hillier, 1990). Restriction endonuclease analysis of isolates from women with bacterial vaginosis has shown that a genetically mixed population is present in the vagina (Nath et al., 1992). Amplified ribosomal DNA restriction analysis (ARDRA) recognized different *G. vaginalis* genotypes. At least three to four genotypes were identified using different restriction enzymes, some of which showed a particular prevalence of distribution in certain centers from which they were collected. Although no correlation was found between bacterial vaginosis and any of the genotypes identified, the ARDRA method could prove to be a useful tool for studying the etiology and epidemiology of *G. vaginalis* (Inganni et al., 1997).

Disease

In 1955, Gardner and Dukes described the newly discovered microorganism, *Haemophilus vaginalis*, which caused a newly defined specific infection called “*Haemophilus vaginalis* vaginitis” previously classified as “nonspecific vaginitis” (Gardner and Dukes, 1955). They also suggested some criteria for the identification of this pathology that still are the basis of the diagnosis today, as described by Amsel et al. (1983). These criteria consider the presence of a homogenous (not

clumpy) vaginal discharge, an elevated pH (5.5–6.0), a positive “whiff” test and the presence of clue cells in the vaginal fluid wet mount preparation. The discoveries of Gardner and Dukes were important in defining the clinical disease and the association of the microorganism *H. vaginalis* with the syndrome. The taxonomy of *Haemophilus vaginalis* underwent changes, that is, from *Haemophilus vaginalis* to *Corynebacterium vaginale* and to its present designation *Gardnerella vaginalis* (Greenwood and Pickett, 1980). Following the introduction of the new techniques for the isolation of anaerobic microorganisms, it appeared evident that “*Haemophilus vaginalis* vaginitis” is not only caused by *G. vaginalis* but also by a polymicrobial complex formed by a variety of anaerobic microorganisms such as *Mobiluncus*, *Bacteroides*, *Prevotella* and *Mycoplasma* species. *Haemophilus vaginalis* vaginitis, also called “nonspecific vaginitis” and “*G. vaginalis* vaginitis,” today might be more appropriately termed “bacterial vaginosis,” which better reflects the microbiological complexity of this clinical disease. The term “vaginosis” is therefore preferred to “vaginitis” because of the absence of clinical signs of inflammation; in addition, inflammatory cells are typically absent in vaginal discharge in bacterial vaginosis (Gardner and Dukes, 1955; Sobel, 1989). The clinical criteria, even in the presence of similar symptomatology (and as abnormal vaginal discharge), can discriminate between vaginitis due to gonococci, yeasts or trichomonads where an increased level of leukocytes is observed and bacterial vaginosis where an increased concentration of anaerobes, a fishy or amine odor and a pH > 4.5 is observed. However, around half the women with this condition are asymptomatic. Diagnosis is best made by microscopic examination of a Gram-stained smear of vaginal secretions. Bacterial vaginosis, determined by the presence of microorganisms which are opportunistic pathogens, is an important vaginal infection because of its potential cause of upper genital tract infection in specific circumstances (Eschenbach, 1993). Recent work has linked bacterial vaginosis to numerous upper genital tract complications such as preterm labor and preterm delivery, preterm premature rupture of the membranes, chorioamnionitis, and postpartum endometritis (Watts et al., 1989; Holst et al., 1994; Kimberlin and Andrews, 1998). The findings from recent prospective randomized trials suggest that treatment of bacterial vaginosis in certain women who are at a high risk of preterm delivery decreases the rate of preterm birth (Hay et al., 1994; Kimberlin and Andrews, 1998). *Gardnerella vaginalis* and the anaerobes associated with bacterial vaginosis are often associated with an increased rate of post-gynecological infection after a hysterectomy

(Kristiansen et al., 1990). The cause of salpingitis is suspected in part to be also by bacterial vaginosis. The consequences of bacterial vaginosis need to be confirmed by more studies, but it has been demonstrated that high concentrations of microorganisms (found in patients with bacterial vaginosis) can infect adjacent tissues.

Most therapeutic trials evaluate treatment outcome at the completion of treatment day 7, or at best, 28–35 days following the termination of therapy, and longer follow-up is rare. Moreover, Hillier and Holmes (1990) reported that 80% of patients with acute bacterial vaginosis can be expected to have a recurrence within 9 months after metronidazole therapy.

In males, *G. vaginalis* has been reported to be the cause of urethritis, prostatitis or urinary tract infections (Smith et al., 1992; Abercrombie et al., 1978; Woolfrey et al., 1986).

A correlation between *G. vaginalis* and activation of human immunodeficiency virus (HIV) type 1 has been found. *Gardnerella vaginalis* lysates were found to significantly stimulate HIV expression in monocytoid cells and in certain T cell lines. The activation of HIV production by *G. vaginalis* suggests that genital infection with *G. vaginalis* increases the risk of HIV transmission by increasing HIV expression in genital tract. This may explain, at least in part, the increased rate of HIV transmission in women with bacterial vaginosis (Hashemi et al., 1999).

Concerning therapy of bacterial vaginosis, treatment is with metronidazole or clavulanic acid-amoxicillin (Augmentin). The indications for treatment of asymptomatic bacterial vaginosis are not clear, but women should probably be treated before any invasive gynecological procedure, including intrauterine contraceptive device insertion.

The Family Propionibacteriaceae: The Genera *Friedmanniella*, *Luteococcus*, *Micrococcus*, *Micropruina*, *Propioniferax*, *Propionimicrobium* and *Tessarococcus*

ERKO STACKEBRANDT AND KLAUS P. SCHAAL

Introduction

A recent systematic-phylogenetic reevaluation of Gram-positive bacteria with a base composition (G+C) of DNA higher than 50 mol% has led to the description of the class Actinobacteria (Stackebrandt et al., 1997) that embraces six orders. The order Actinomycetales (Buchanan 1917, emend Stackebrandt, Rainey and Ward-Rainey 1997) has been defined to include 10 suborders, one of which is Propionibacterineae, containing the family Propionibacteriaceae (Delwiche 1957, emend Rainey, Ward-Rainey and Stackebrandt, 1997) with the genera *Propionibacterium* (Orla-Jensen, 1909), *Luteococcus* (Tamura et al., 1994), *Micrococcus* (Nakamura et al., 1995) and *Propioniferax* (Yokota et al., 1994). Recently, four new genera have been added to the family, i.e., *Friedmanniella* (Schumann et al., 1997), *Tessarococcus* (Maszenan et al., 1999b), *Micropruina* (Shintani et al., 2000) and *Propionimicrobium* (Stackebrandt et al., 2002; Table 1). As the majority of the recently described species are defined by a single strain only, the metabolic properties of the description may change with the inclusion of new strains. Thus, it cannot be decided whether properties described for the type strain will allow affiliation of novel isolates to species.

Membership to the family is based on distinct phylogenetic position and an exclusive set of some 16S rDNA signature nucleotides not found in other families (Stackebrandt et al., 1997). As is also true for nonmolecular diagnostic features, these signatures should be reevaluated with new members added to the family.

Members of the Propionibacteriaceae thrive in diverse habitats, covering human epidermal surfaces, dairy products, silage, soil, water, Antarctic sandstone and sewage treatment plants. They are either aerobic or facultatively anaerobic, have different morphologies, and exhibit different peptidoglycan types and variations, and the base composition of DNA ranges between 53 and 73 mol%. However, with respect to chemotaxo-

nomic properties (such as the combination of patterns of polyamines [Busse and Schumann, 1999], major menaquinones and fatty acids), members of the Propionibacteriaceae appear rather homogeneous. As judged from phylogenetic analyses (Fig. 1) and the occurrence of certain chemotaxonomic markers, the genus *Propionibacterium* appears to be diverse: the intrageneric 16S rDNA differences separating the most unrelated species of the *Propionibacterium* (90–94% similarity) are as low as those separating the other genera of the family. Within *Propionibacterium*, three clearly separated clusters emerge which do not follow the classical separation into dairy propionibacteria and the cutaneous propionibacteria commonly found on skin.

Applying different treeing algorithms to the dataset of 28 almost complete 16S rDNA sequences, including those of 21 validly described type strains (Table 1), the family contains two subgroups, one embracing members of *Propionibacterium*, the other embracing representatives of the other genera. While the phylogenetic coherence of multispecies genera is maintained, the relative order may change at which genera emerge. Only the position of certain species, i.e., *Propionibacterium lymphophilum*, *Propionibacterium propionicum* and *Tessarococcus bendigoensis*, is less stable, and their position changes with the algorithm applied (Fig. 1). The distinct phylogenetic position of *P. lymphophilum* (branching with *Luteococcus japonicus*) has also been depicted by Dasen et al. (1998). The presence of distinct chemotaxonomic properties in *P. lymphophilum* and the remote phylogenetic position led to the reclassification of this species as *Propionimicrobium lymphophilum* (Stackebrandt et al., 2002).

The type strains of *Friedmanniella antarctica*, *Micrococcus phosphovorans*, *Luteococcus japonicus* and *Propioniferax innocua* were included in a sequencing study on ribonuclease P RNA (Yoon and Park, 2000). Surprisingly, *Luteococcus japonicus* possessed a nucleotide

Table 1. Validly published species in the family Propionibacteriaceae.

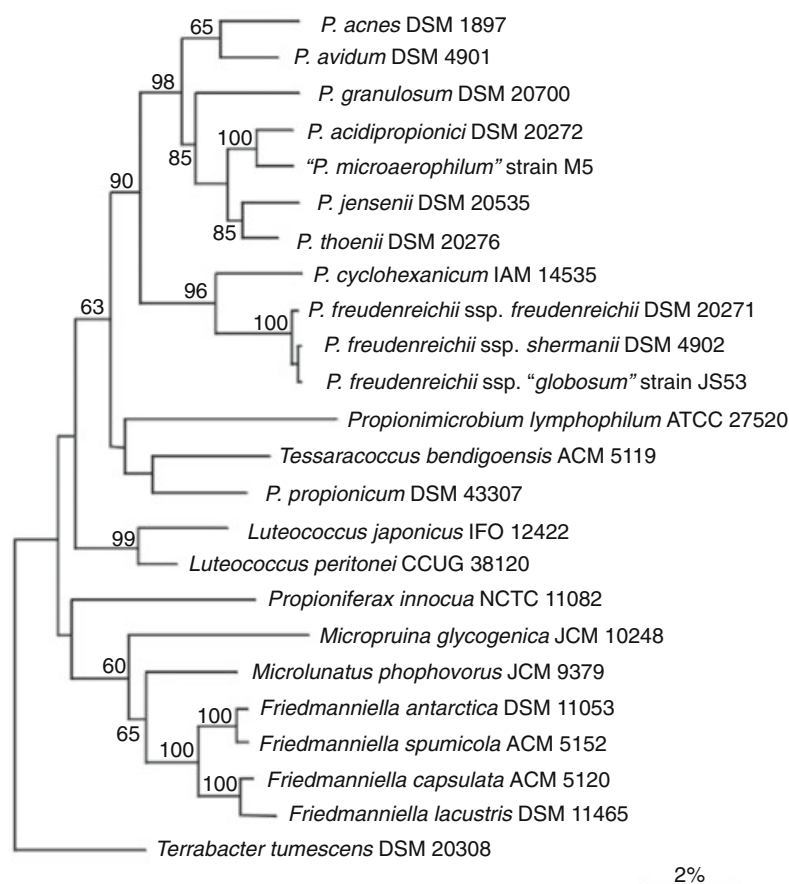

Fig. 1. Distance matrix analysis (De Soete, 1983) of almost complete 16S rDNA sequences of species of the family Propionibacteriaceae. Numbers refer to bootstrap values (500 resamplings).

sequence that was nearly identical to that of *Nocardioides jensenii* (>99% similarity), a member of the sister clade of Propionibacteriaceae. The sequences of the type strains of the other

three genera were less closely related (81.0–83.8% similarity) but clustered together to the exclusion of other LL-diaminopimelic acid (A_2pm)-containing actinomycetes.

This chapter will be restricted to genera other than *Propionibacterium*. The authors feel that the clinical and biotechnological significance of members of this genus merit a separate chapter for the genus *Propionibacterium*.

The Genus *Friedmanniella*

The genus *Friedmanniella* contains four Gram-positive, nonmotile, coccoid, packet-forming species, two of which, viz., *F. antarctica* (Schumann et al., 1997) and *F. lacustris* (Lawson et al., 2000), originate from Antarctic environments, while the other two species, viz., *F. spumicola* and *F. capsulata* (Maszenan et al., 1999a), were isolated from sewage treatment plants in Australia. These organisms were described as members of the same genus mainly on phylogenetic, chemotaxonomic and morphological evidence. They exhibit the same rare peptidoglycan type A3 γ , in which one glycine residue is defining in the interpeptide bridge while a second one is found at position 1 of the peptide subunit. The same peptidoglycan type defines the genera *Microbunatus* and *Tessaracoccus*, as well as *Propionibacterium propionicum*. The strains accumulate polyphosphate (*F. lacustris* has not been investigated). The phylogenetic neighbors of *Friedmanniella* species are members of *Microbunatus* and *Micropruina*. Interestingly, the two Antarctic species do not cluster together, but each of them is more closely related to species isolated from Australian activated sludge. *Friedmanniella antarctica* has 98.8% 16S rDNA similarity with *F. spumicola*, and the type strains share 50% DNA-DNA reassociation, as determined by the renaturation method (Maszenan et al., 1999a). *Friedmanniella capsulata* shares 99.0% 16S rDNA similarity with *F. lacustris*; on DNA-DNA hybridization are not available. Reassociation values obtained for *F. capsulata* with *F. antarctica* and *F. spumicola* are 27 and 29%, respectively. Thus, the overall DNA relatedness is in accord with the phylogenetic clustering as unravelled by gene sequence analysis.

Isolation and Maintenance

Owing to their isolation from different habitats (sandstone, hypersaline lake and activated sludge) and by different research groups, the isolation procedures are quite different.

Friedmanniella antarctica AA-1043^T (DSM 11053^T) has been isolated by Peter Hirsch (Kiel, Germany) from a sandstone sample containing a cryptoendolithic microbial community at 1,600 m above ocean level from the Linnaeus Terrace, McMurdo Dry Valleys, Asgard Range,

Transarctic Mountains, Antarctica. The pH of the sampling site was 4.8. Loosened material was sprinkled onto the surface of PYGV (pH 6.9) agar plates (see below). The plates were incubated for 5 months at 9°C in dim light. Individual colonies were picked and purified on PYGV agar after 5 months incubation at 4–6°C. Cells can also be cultivated on Rich medium (DSMZ medium 736; Yamada and Komagata, 1972), trypticase soy broth (TSB) medium (Difco), enriched nutrient broth (Serva), and enriched nutrient agar (pH 7.2; Serva). Biomass for chemotaxonomic, physiological and most of the biochemical studies was produced on R-agar slants at 22°C. For long-term storage, freeze drying, followed by storage at 8°C, is recommended.

Medium PYGV

(DSM 621; Staley, 1968)

Mineral salt sol. ("Hutner/Cohen-Bazire")	20.00 ml
Peptone (Bacto)	0.25 g
Yeast extract (Bacto)	0.25 g
Agar (Bacto)	15.00 g
Distilled water	965.00 ml

Sterilize 20 min. at 121°C. After cooling to 60°C, add the following to the medium:

Glucose sol. (2.5%, sterile-filtered)	10.00 ml
Vitamin sol. (double conc.)	5.00 ml

Adjust pH to 7.5 (the medium is only weakly buffered; one needs approx. 10 drops of 6N KOH per liter of medium).

Mineral Salt Solution

Nitritotriacetic acid (NTA)	10.00 g
MgSO ₄ · 7H ₂ O	29.70 g
CaCl ₂ · 2H ₂ O	3.34 g
Na ₂ MoO ₄ · 2H ₂ O	12.67 mg
FeSO ₄ · 7H ₂ O	99.00 mg
Metallic salt solution	50.00 ml
Distilled water	900.00 ml

Dissolve NTA first by neutralizing with KOH, then add other salts. Adjust pH to 7.2 with KOH or H₂SO₄. Adjust volume to 1000.0 ml with distilled water.

Metallic salt solution

Na-EDTA	250.000 mg
ZnSO ₄ × 7 H ₂ O	1095.000 mg
FeSO ₄ × 7 H ₂ O	500.000 mg
MnSO ₄ × H ₂ O	154.000 mg
CuSO ₄ × 5 H ₂ O	39.200 mg
Co(NO ₃) ₂ × 6 H ₂ O	24.800 mg
Na ₂ B ₄ O ₇ × 10 H ₂ O	17.700 mg
Distilled water	100.000 ml

Dissolve the EDTA and add a few drops of concentrated H₂SO₄ to retard precipitation of the heavy metal ions.

Vitamin Solution (double conc.)

Biotin	4.00 mg
Folic acid	4.00 mg
Pyridoxine-HCl	20.00 mg
Riboflavin	10.00 mg
Thiamine-HCl · 2H ₂ O	10.00 mg

Nicotinamide	10.00 mg
D-Ca-pantothenate	10.00 mg
Vitamin B ₁₂	0.20 mg
<i>p</i> -Aminobenzoic acid	10.00 mg
Distilled water	1.0 liter

Store in the dark and cold (5°C).

Friedmanniella spumicola strain Ben 107^T (ACM 5121^T) was isolated by micromanipulation (Skerman, 1968) from the stable surface foam of an activated sludge plant aerobic reactor treating mainly wastewater from an orange-juice-processing plant in Mildura, Victoria, Australia. *Friedmanniella capsulata* strain Ben 108^T (ACM 5120^T; DSM 12936^T) was micromanipulated from an activated sludge biomass sample from Haman Island, Queensland, Australia. Both strains grew on standard methods agar (SMA [Difco]) supplemented with 1% sterile horse serum at 25°C, and colonies developed after 7–10 days. Subsequent purification was done on R2A agar (see below). Cells were stored at –80°C in R2A medium in 20% glycerol. At the DSMZ, for short-term storage, strains are suspended in trypticase soy yeast extract medium, and for long-term storage, cultures are freeze dried.

Medium R2A (DSMZ Medium 830)

Yeast extract	0.50 g
Proteose peptone (Difco no. 3)	0.50 g
Casamino acids	0.50 g
Glucose	0.50 g
Soluble starch	0.50 g
Na-pyruvate	0.30 g
K ₂ HPO ₄	0.30 g
MgSO ₄ · 7H ₂ O	0.05 g
Agar	15.00 g
Distilled water	1.0 liter

Adjust to pH 7.2 with crystalline K₂HPO₄ or KH₂PO₄ before adding agar. Add agar, heat medium to boiling to dissolve agar, and autoclave for 15 min at 121°C.

The species *F. lacustris* EL-17A^T (DSM 11465^T) was isolated from an Ekho Lake water sample taken at 1 m depth, collected in January 1990. The hypersaline and meromictic lake is located in the ice-free area of the Vestfold Hills in East Antarctica. The sample had a salinity of 9.5%, a temperature of 2.8°C, and a pH of 8.04. Enrichment was done in medium PYGV (pH 8.0; Staley, 1968), prepared with filtered water from the sampling site. Growth occurred within 12 days at 15°C, and single colonies were subcultured on the same medium. Freeze drying, followed by storage at 8 °C, was the long-term storage method.

Morphological and Cultural Characteristics

On PYGV medium, single cells of strain *F. antarctica* DSM 11053^T are spherical or nearly spherical and range from 1.2 to 1.5 µm in diam-

Fig. 2. Phase contrast photomicrographs of *Friedmanniella antarctica* DSM 11053^T. Bar = 10 µm. (A) Clusters grown on PYGV broth for 4 weeks at 20°C, (B) clusters grown on R medium for 5 days at 22°C, and (C) single cells, partly dividing. Bars = 10 µm. (Reproduced with permission from P. Schumann; Schumann et al., 1997.)

eter (Fig. 2C). Occasionally, larger cells are observed that are 2.0–2.2 µm in diameter. On R agar, the cells vary from 0.5 to 2.2 µm in diameter and are ellipsoidal. Generally, the cells occur in packets (Figs. 2A and 2B) which result from cell division in three perpendicular planes. The packets adhere to one another, forming clusters. On R agar, colony color is bright orange but less intense when the organism is grown in the dark; in aging cultures, the color changes from orange to yellow and finally to faint yellow.

On PYGV medium prepared with saline lake water, colonies of *Friedmanniella lacustris* DSM

Fig. 3. Electron micrograph, C/PT shadowed, of *Friedmanniella lacustris* DSM 11465^T. Bar = 1 μ m. (Reproduced with permission from P. Hirsch; from Lawson et al., 2000.)

Fig. 4. Scanning electron micrograph of cell aggregates of (A) *Friedmanniella spumicola* ACM 5121^T and (B) *F. capsulata* ACM 5120^T. Bar = 2 μ m. (Reproduced with permission from R. J. Seviour; from Maszenan et al., 1999.)

11465^T are orange. Cells are often arranged in packets, but short rods may also be formed, 0.9–1.3 \times 0.9–1.5 μ m (Fig. 3). Packets are often surrounded by extracellular polymer.

Friedmanniella spumicola ACM 5121^T and *F. capsulata* ACM 5120^T grow as yellow to pale orange colonies on different media. Both organisms grew as clusters of coccoid cells (Figs. 4a and

Fig. 5. TEM micrograph of a thinly sectioned cryosubstituted cell cluster of strain *Friedmanniella capsulata* ACM 5120^T, displaying large amounts of the dense extracellular capsular material that surrounds the cluster and divides it internally into smaller packages of cells. Small electron-dense granules (arrows) are present in the cytoplasm. Bar = 1 μ m. (Reproduced with permission from R. J. Seviour; from Maszenan et al., 1999.)

4b, respectively). Spherical cells have a diameter of 0.5–1.4 and 0.6–1.2 μ m for strains ACM 5121^T and ACM 5120^T, respectively. Cells remain closely associated with each other after cell division as a result of production of extracellular capsular material (Fig. 5).

Physiological, Biochemical and Chemotaxonomic Properties

Friedmanniella antarctica, *F. capsulata* and *F. spumicola* were characterized by the API ZYM (bioMérieux) and Microbact (Oxoid) systems. Carbon utilization test of the latter two species was performed with the BIOLOG GN and GP (Special Diagnostics) systems and compared to the methods of Goodfellow (1971). The results obtained by these two different methods agreed in most cases (Maszenan et al., 1999a), though certain differences were noticed in the negative response of the BIOLOG system to the utilization of glycerol, maltose, melizitose, sucrose and trehalose. *Friedmanniella lacustris* was characterized by using the methods of Labrenz et al. (1999) developed for the characterization of a new Gram-negative species from Ekho Lake, i.e., *Roseovarius tolerans*. Other tests followed Smibert and Krieg (1994), Bradford (1976) and the BIOLOG GP system. Chemotaxonomic properties (Table 3) were determined using methods as listed in Table 2.

A detailed listing of properties is indicated in the species descriptions (Schumann et al., 1997;

Table 2. Methods used in the determination of chemotaxonomic properties.

^aAccording to Schleifer and Kandler (1972).

^bKusano et al. (1997).

Maszenan et al., 1999a; Lawson et al., 2000). Table 4 only lists those properties which have also been determined for the majority of phylogenetically related taxa with spherical morphology. The original descriptions list many more reactions which are helpful in the identification of novel isolates. The metabolic properties clearly differentiate between the four species, though the intraspecies diversity of strains has yet to be elucidated with more strains affiliated. The metabolically most versatile organism is *Friedmanniella capsulata* that utilizes most of the substrates provided by the BIOLOG GN and GP Microplate panels, followed by *Friedmanniella lacustris*. According to 16S rDNA analysis, these two species are phylogenetic neighbors. *Friedmanniella spumicola* utilizes the BIOLOG and GP Microplate substrates poorly only, while *F. antarctica* shows almost no positive reaction (except for formate, xylose, ribose, arabinose, erythritol, D-saccharic acid, formic acid, adonitol, 3-methyl glucose, bromosuccinic acid and L-proline). Except for *F. antarctica*, each of the species exhibits certain characters which clearly distinguished it from the other species of the genus. They can also be distinguished from each other by the primary structure of their 16S rDNA sequence. *Friedmanniella lacustris* has a vitamin requirement of biotin, thiamine and nicotinic acid, and it hydrolyzes gelatin and tolerates up to 6% (w/v) NaCl; *Friedmanniella spumicola* has a complex pattern of menaquinones (Table 3) and a low DNA base composition of 69 mol%. Growth of both *F. spumicola* and *F. capsulata* is inhibited by NaCl, and the latter utilizes a significant portion of carbohydrates provided by commercial kits.

The Genus *Luteococcus*

This genus comprises two species, which are morphologically distinct but share chemotaxonomic and phylogenetic similarities. The type species *Luteococcus japonicus* (Tamura et al., 1994), containing two strains (IFO 12422^T and IFO15385), has been isolated from soil and water and is spherical. *Friedmanniella peritonei* (Collins et al., 2000) has been isolated from a human specimen and the type (and only) strain CCUG 38120^T exhibits a pleomorphic rod morphology. The 16S rDNA similarity for these two type strains is 96% (at least 3% higher than similarities separating these two species from other members of the family Propionibacteriaceae), which justified the affiliation of these morphologically different species to the same genus. The most salient feature of the genus is the presence of monounsaturated long-chain fatty acids (>80% of total), i.e., C_{15:1}, C_{16:1}, C_{17:1}, and C_{18:1}.

While C_{16:1} predominates in *L. japonicus* (36–60%), C_{17:1} (38%) is the major fatty acid in *L. peritonei*.

Isolation and Maintenance

Strain IFO 12422^T was isolated from soil on Tokara Island, Japan, while strain IFO15385 was originally obtained from water for brewing “miyamizu” in Hyogo prefecture, Japan (Oda et al., 1935). Miyamizu is short for “Nishinomiya no mizu,” the water of Nishinomiya, used for the production of Nada sake. Both strains were routinely maintained on nutrient agar (Difco) or grown in shake cultures in nutrient broth (Difco). Strain CCUG 38120^T was isolated from human peritoneum during a fetal autopsy and obtained from the culture collection of the University of Göteborg, Sweden. For long-term storage, cultures were lyophilized and stored at 8°C. Cells were grown on chocolate agar at 30°C for fatty acid analysis.

Morphological and Cultural Characteristics

Colonies of *Friedmanniella japonicus* is cream colored to yellow. Cells are 0.7–1.0 µm in diameter, occurring singly, in pairs or in tetrads (Figs. 6 and 7). Cells of *Friedmanniella peritonei*, on the other hand, are nonmotile pleomorphic rods (dimensions and color of colonies not indicated in the original description).

Physiological, Biochemical and Chemotaxonomic Properties

A detailed listing of properties is indicated in the species description (Tamura et al., 1994; Collins et al., 2000). Chemotaxonomic properties (Table 3) were determined using the methods listed in Table 2. Table 4 only lists those properties which have also been determined for the majority of phylogenetically related taxa.

The Genus *Microlunatus*

This genus has been described to accommodate the Gram-positive, nonmotile, coccoid and aerobic organism *Microlunatus phosphovor* (Nakamura et al., 1995). The description is based on the properties of two strains NM-1 and NM-2; the latter strains differ from the type strain NM-1^T (JCM 9379^T) only by flocculent growth. These strains, isolated from activated sludge in Japan, are chemoorganotrophic organisms that store polyphosphate. In contrast to other spherical members of Propionibacteriaceae, which predominantly form tetrads or packets, *M. phosphovor* occurs singly or in pairs. The original

Fig. 6. Phase contrast A) and scanning electron micrograph B) of *L. japonicus* IFO 12422^T grown on yeast extract-malt extract agar. Bars = 3 and 1 μm , respectively. (Reproduced with permission from T. Tamura; from Tamura et al., 1994.)

description did not link *M. phosphovor*us to the genera *Luteococcus*, *Propioniferax* and *Propionibacterium*, but it was more closely affiliated to *Aeromicrobium* and *Nocardioides*, later included in the family Nocardioideaceae (Stackebrandt et al., 1997). Only with the inclusion of novel members of Propionibacteriaceae did the membership of *Micrococcus* to this family become obvious. Two other strains have recently been investigated with respect to the 16S rDNA analysis. Strain UMT-1 (partial sequence; 16S rDNA accession number D32041) is reported to be a strain of *M. phosphovor*us. Strain Y-73 (16S rDNA accession number D50065), proposed as “*Micrococcus confertus*” (but not yet validly published), shows 98% 16S rDNA sequence similarity to *M. phosphovor*us.

Isolation and Maintenance

The strains were first mentioned as tentative members of *Micrococcus* or *Arthrobacter* in a study which reported on polyphosphate-

Fig. 7. Thin section electron micrographs of *L. japonicus* IFO 12422^T. Cell division occurs alternately in two planes: the first division (A) and the second division (B). Bar = 0.2 μm . (Reproduced with permission from T. Tamura; from Tamura et al., 1994.)

accumulating bacteria and their ecological characteristics in the activated sludge process (Nakamura et al., 1989). However, these organisms differed from members of these Gram-positive genera in chemotaxonomic properties and from *Acinetobacter* strains by their ability to release polyphosphate after the addition of glucose. The isolation of strains NM-1^T and NM-2 was described by Nakamura et al. (1991).

The strains were cultured aerobically at 25°C in the following medium.

Micrococcus Medium (DSM Medium 776; Nakamura et al., 1995)

Glucose	0.5 g
Peptone	0.5 g
Yeast extract	0.5 g
Na-glutamate	0.5 g
KH ₂ PO ₄	0.5 g
(NH ₄) ₂ SO ₄	0.1 g
MgSO ₄ · 7H ₂ O	0.1 g
Distilled water	1.0 liter

Adjust pH to 7.0.

Cells are freeze dried and stored at 8°C.

Fig. 8. A) Phase contrast photomicrograph of *Micrococcus phosphovorius* JCM 9379^T. B) Scanning electron micrographs of a single cell and C) of a pair of cells of JCM 9379^T. Bars = 1 μ m. (Reproduced with permission from K. Nakamura; Nakamura et al., 1995.)

Morphological and Cultural Characteristics

The type strain JCM 9379^T is characterized by coccoid cells (0.8–2.0 μ m in diameter) that occur singly or in pairs (Fig. 8). Sometimes, cells are arranged in small irregular clusters. Cell size depends on the growth stage; cells are larger at the early stage of a culture than at the late stationary phase. The type of cell division is unusual; thin-section electron microscopy revealed a cell wall-like structure in the middle of the cell. The type strain exhibits low growth rates even under optimal growth conditions. The doubling time is about 13 h in a liquid medium at pH 7.0 and 25°C. Visible colonies appear on agar plates after 5 days of incubation. The colonies are circular (diameters, 0.5–1 mm), smooth, convex, and cream colored at the early stage of growth. Colonies are yellowish and 1–2 mm in diameter after 10–14 days of incubation.

Physiological, Biochemical and Chemotaxonomic Properties

Utilization of substrates was determined by adding 1.8 g of each substrate to a basal medium that is a modification of DSM medium 776.

Basal Substrate Utilization Medium (Modified DSM Medium 776)

Peptone	0.1 g
Yeast extract	0.1 g
KH ₂ PO ₄	0.44 g
(NH ₄) ₂ SO ₄	0.1 g
MgSO ₄ · 7H ₂ O	0.4 g
Distilled water	1.0 liter

Adjust pH to 7.0.

Chemotaxonomic properties (Table 3) were determined using methods listed in Table 2. A detailed listing of properties is indicated in the species description (Nakamura et al., 1995); for comparative reasons, some of the carbon utiliza-

tion data have been generated by Maszenan et al. (1999). Table 4 only lists those differentiating properties which have also been determined for the majority of phylogenetically and morphologically related taxa.

The Genus *Micropruina*

The genus *Micropruina* with *M. glycogenica* as the only species has also been isolated from an anaerobic-aerobic sequential batch biofilter reactor exhibiting enhanced biological phosphorous removal (Shintani et al., 2000). This Gram-positive, nonmotile spherical species is represented by a single strain Lg2^T (JCM 10248^T) which lies phylogenetically between *Friedmanniella antarctica* and *Micrococcus phosphovorius*. The position remained stable in the maximum-likelihood and consensus tree (Felsenstein, 1993) analyses when sequences of all type strains of Propionibacteriaceae are included (Fig. 1). As also observed for *Tessarcoccus bendigoensis*, *M. glycogenica* is a slow-growing organism. It accumulates glycogen intracellularly. In contrast to most other members of the family, *meso*- and not *LL*-diaminopimelic acid (A₂pm) is the diagnostic amino acid in the peptidoglycan.

Recently, the 16S rDNA sequences of three novel strains have been published, which are phylogenetically related to *M. glycogenica*. Strain VeSm15 originated from anoxicogenic soil containing rice plants (Chin et al., 1999), in which it appeared to be abundant. Strain VeSm15 grew fermentatively and produced acetate and propionate from carbohydrates. The 16S rDNA analysis (accession number AJ229243) revealed 96% similarity with that of *M. glycogenica*. Strain VeSm15 is the closest relative to the uncultured bacterium SJA-1 (98% similarity).

The sequence of clone SJA-1 (accession number AJ009505), recovered from DNA isolated from a fluidized bed reactor inoculated with an anaerobic consortium transforming trichlorobenzene (von Wintzingerode et al., 1999), was 96% similar to the *M. glycogenica* sequence. Due to the fact that at the time of publication of SJA-1, *Micropruina* had not been published, the 16S rDNA sequence was shown to be related to that of *Micrococcus phosphovor*. The third member is an unidentified bacterium sbr-gs28 (C. Jeon and J. Park, unpublished observation; accession number AF281118) displaying between 94 and 95% sequence similarity to the other members of the *Micropruina* lineage.

Isolation and Maintenance

The type strain has first been isolated by Liu et al. (1997) on *Micrococcus* (NM-1; DSM medium 776) agar (Nakamura et al., 1995). This medium, omitting agar, was subsequently used in the determination of morphological and metabolic properties. Long-term conservation is achieved by freeze-drying, followed by storage at 8°C.

Morphological and Cultural Characteristics

Strain JCM 1028^T grows slowly on NM-1 medium, developing white and punctated colonies after 2–3 weeks. Growth is very slow in the liquid NM-1 medium under aerobic conditions. The strain could grow in the presence of NaCl up to 3.00% (w/v). Spherical cells (0.5–2.2 µm in diameter) occur in pairs, packets or clusters and are surrounded by a capsule. When observed by electron microscopy, a septum is often seen in the middle of each growing cell (Fig. 9).

Fig. 9. Transmission electron micrograph of *Micropruina glycogenica* JCM 10248^T showing capsules outside the cells. Cells were grown in NM-1 medium at 30°C under aerobic conditions. Bar = 1 µm. (Reproduced with permission from K. Nakamura; from Shintani et al., 2000.)

Physiological, Biochemical and Chemotaxonomic Properties

A detailed listing of properties is indicated in the species description (Shintani et al., 2000). Chemotaxonomic properties (Table 3) were determined using methods as listed in Table 2. Table 4 only lists those properties which have also been determined for the majority of phylogenetically related taxa. Glycogen has been identified as a storage product; the glycogen content increased significantly in the exponential phase of growth and gradually decreased in the stationary phase. Up to 8.4% of cellular glycogen was determined, based on dry cell weight.

The Genus *Propioniferax*

Propionibacterium innocuum, a Gram-positive, non-acid fast, nonmotile, nonsporeforming organism, was isolated from human epidermal surface by Pitcher and Collins (1991). It was affiliated to *Propionibacterium* because of the presence of genus-specific characteristics such as the presence of LL-A₂pm in the peptidoglycan, coryneform morphology, base composition of DNA, and the formation of propionic acid as the main endproduct of glucose fermentation. 16S rRNA analysis placed *P. innocuum* as a remotely related member of the genus *Propionibacterium*. However, outside reference organisms that would have shown the position of *P. innocuum* in relation to other coryneform and actinomycete species were not included in the phylogenetic analysis. With the description of *Luteococcus japonicus*, *P. innocuum* emerged as the nearest phylogenetic neighbor (94.5% 16S rDNA similarity), and both species branched as a sister clade to *Propionibacterium* species. In the light of this information, certain properties of *P. innocuum* were reevaluated: in contrast to the descriptions of most *Propionibacterium* species (Cummins and Johnson, 1986; Charfreitag et al., 1988; Kusano et al., 1997), strains of *P. innocuum* showed aerobic and facultatively anaerobic growth, contained arabinose in cell wall hydrolysates, and did not require blood, serum, or Tween 80 for growth. As it differed from *Luteococcus* in morphology and from other LL-A₂pm-containing taxa, such as members of *Aeromicrobium* and *Nocardioides*, and by the formation of propionic acid, *P. innocuum* was reclassified as the type species of a new genus *Propioniferax* and renamed "*Propioniferax innocua*" (Yokota et al., 1994).

Isolation and Maintenance

Strains of *P. innocua* originated from human skin, isolated from laboratories in Philadelphia (United States), Leiden (The Netherlands),

and London (United Kingdom). Strains were routinely cultured aerobically on nutrient agar (Oxoid) at 37°C. Anaerobic growth on nutrient agar at an atmosphere of 95% H₂ and 5% CO₂ was much reduced. Cells also grow well in CPY broth (casein peptone, 10 g; yeast extract, 5 g; glucose, 5 g; NaCl, 5 g; and H₂O, 1 liter; pH 7.2) and tryptone soy broth (Difco), supplemented with 1% yeast extract.

Morphological, Cultural, Physiological and Chemotaxonomic Characteristics

Cells are pleomorphic rods appearing in clusters and V forms. Colonies are white, shining, and convex to domed. The optimum growth temperature is approximately 37°C. Growth also occurs at 10–40°C. The species is facultatively anaerobic, but substantial growth occurs aerobically. On nutrient or horse blood agar, colonies are approximately 0.5–3 mm in diameter. The principal carboxylic acid produced from glucose is propionic acid. Methods used in chemotaxonomic analyses are indicated in Table 2, and data are presented in Table 3.

The Genus *Propionimicrobium*

Originally described as “*Bacillus lymphophilus*” (Torrey, 1916), “*Corynebacterium lymphophilum*” (Torrey, 1916) Ebersson 1918 and “*Mycobacterium lymphophilum*” (Torrey, 1916) Krasil’nikov 1949, strain VIP 0202 has been included in a taxonomic study by Johnson and Cummins (1972) on coryneforms and propionibacteria. The type strain ATCC 27520^T was tentatively classified as *Propionibacterium lymphophilum*, because of low DNA reassociation with members of *Corynebacterium*, anaerobic growth, and the formation of propionic acid. A combination of chemotaxonomic distinctness and phylogenetic position, i.e., sequence analysis of 16S rDNA, has been the main basis for the description of novel actinobacterial genera; in the past decade, *Propionibacterium lymphophilum* was transferred to a new genus *Propionimicrobium*. *Propionimicrobium lymphophilum* DSM 4309^T shares lower than 91.8% sequence similarity with the other *Propionibacterium* species (Dasen et al., 1998), which themselves show higher than 93% similarity among each other. Depending upon the algorithm used, analysis of the 16S rDNA indicates that *P. lymphophilum* either forms the deepest branch of the genus (as shown by neighbor-joining, Felsenstein, 1993; Koussémon et al., 2001) or branches even among the other genera of Propionibacteriaceae as shown by maximum-likelihood (Felsenstein, 1993) or distance matrix analyses (De Soete, 1983; Fig. 1).

Isolation and Maintenance

The organism was first isolated by Torrey (1916) from lymph glands in a Hodgkin’s disease patient. Later, strains were also isolated from urinary tract infections and the mesenteric ganglion of a monkey inoculated with “*Actinobacterium*.” Strains of the species have also been reported to thrive in soil of rice paddy fields (Haashi and Furusaka, 1980) and in preparations of green olives (Cancho et al., 1980), but as pointed by Cummins and Johnson (1986), the identification of these strains did not include the verification of the distinct cell wall composition and base composition of DNA.

The organism is anaerobic, producing no growth on agar surface incubated aerobically, but growth develops in deep broth incubated aerobically. Cells are maintained on modified Peptone-Yeast-Glucose agar (DSMZ medium 104, see below) or Columbia agar containing 5% defibrinated sheep blood (Becton Dickinson and Company). Plates are sealed in Anerocult A (Merck) bags. For storage, cultures are frozen in 20% glycerol and maintained at –80°C or lyophilized.

Modified Peptone-Yeast-Glucose Medium (DSMZ Medium 104)

Trypticase peptone	5.00 g
Peptone	5.00 g
Yeast extract	10.00 g
Bf extract	5.00 g
Glucose	5.00 g
K ₂ HPO ₄	2.00 g
Tween	801.00 ml
Resazurin	1.00 mg
Salt solution (see below)	40.00 ml
Distilled water	950.00 ml
Hemin solution (see below)	10.00 ml
Vitamin K1 solution (see below)	0.20 ml
Cysteine-HCl · H ₂ O	0.50 g

The vitamin K1, hemin solution, and cysteine are added after the medium has been boiled and cooled under CO₂. Adjust pH to 7.2 using 8 N NaOH. Distribute under N₂ and autoclave.

Salt Solution

CaCl ₂ · 2H ₂ O	0.25 g
MgSO ₄ · 7H ₂ O	0.50 g
K ₂ HPO ₄	1.00 g
KH ₂ PO ₄	1.00 g
NaHCO ₃	10.00 g
NaCl	2.00 g
Distilled water	1.0 liter

Hemin Solution

Dissolve 50 mg of hemin in 1 ml of 1 N NaOH; make up to 100 ml with distilled water. Store refrigerated.

Vitamin K1 Solution

Dissolve 0.1 ml of vitamin K1 in 20 ml of 95% ethanol and filter sterilize. Store refrigerated in a brown bottle.

Morphological and Cultural Characteristics

After a 4-d incubation at 37°C, colonies (≤ 1 mm in diameter) on Columbia agar are punctiform and on horse blood (≤ 0.5 mm), punctiform, circular, entire, convex to pulvinate, glistening and smooth. Cells are pleomorphic rods (0.5–0.8 μm in width \times 1–2.5 μm in length), often diphtheroid or club-shaped. Cells may be coccoid. PYG broth cultures (24 h) are turbid, becoming clear, with a ropy sediment and terminal pH of 5.4–5.7.

Cells may occur singly, in pairs or short chains, in V or Y configurations, or in clumps. A drawing of the morphology is given by Holdeman et al. (1977).

Physiological, Biochemical and Chemotaxonomic Properties

Main endproducts of glucose fermentation are propionic acid, acetic acid, succinic acid and isovaleric acid. Formic acid is produced in smaller amounts. Physiologically this species can be differentiated from members of the genus *Propionibacterium* by the lack of esculin hydrolysis and indole production as well as by a combination of acid production from adonitol, erythritol, maltose and ribose (Holdeman et al., 1977). Johnson and Cummins (1972) found lysine instead of diaminopimelic acid as the dicarboxylic amino acid of the peptidoglycan. Using the methods of Schleifer and Kandler (Schleifer and Kandler, 1972; Table 2), we confirmed the presence of lysine and demonstrated the peptidoglycan type to be A4 α (Lys-Asp) in which aspartic acid forms the interpeptide bridge (Table 3). Using the method of Meshbah et al. (1989), it was shown that the DSMZ culture has a DNA base composition of 56 mol% G+C, which is slightly higher than 53–54 mol% reported for VIP 202 (Johnson and Cummins, 1972). Investigation of the principal isoprenoid quinone (Stackebrandt et al., 2002) revealed MK-9(H₄), which is present in all members of the family Propionibacteriaceae. Major fatty acids, determined according to Miller and Berger (1984), are C_{18:1 ω 9c} (30%), *anteiso*-C_{15:0} (29%) and C_{16:0} (15%); smaller amounts (>2–<5%) are C_{14:0}, *i*-C_{15:0}, *ai*-C_{17:0}, and C_{18:1 ω 7c}. This composition differs significantly from those reported for *Propionibacterium* strains, in which either branched fatty acids (Moss et al., 1969) or ω -cyclohexane (Kusano et al., 1997) dominate.

The Genus *Tessaracoccus*

The genus *Tessaracoccus* with the single species *T. bendigoensis* has been described for the non-motile, coccoid, facultatively anaerobic Gram-positive strain Ben 106 (ACM 5119^T, DSM 12906^T; Maszenan et al., 1999b), isolated from

activated sludge biomass. The sludge, originating from the biological nutrient removal plant in Bendigo, Australia, had been processed in a laboratory-scale sequencing batch reactor. The morphology of this strain, i.e., spherical or clusters of cocci arranged in tetrads, resembles that of the Gram-negative so-called “G-bacteria” (Cech and Hartman, 1993; Carucci et al., 1994), commonly detected in activated sludge samples.

The G-bacteria constitute a phylogenetically diverse group of organisms belonging to the actinobacteria and Proteobacteria (Seviour et al., 2000). The description of *Tessaracoccus bendigoensis* extends the range of spherical species described to thrive in similar habitats, e.g., four Gram-negative species of *Amaricoccus* (Maszenan et al., 1997) from wastewater treatment plants in Italy, Czech Republic, Macau and Australia and the Gram-positive species *Micrococcus phosphovor* (Nakamura et al., 1995) from activated sludge and *Microsphaera multipartita* (Yoshimi et al., 1996) from sugar-containing synthetic wastewater, both from Japanese plants. While *Amaricoccus* is a member of the α -subclass of Proteobacteria, *Microsphaera* is a member of the actinobacterial suborder Frankineae, and *Micrococcus* belongs to Propionibacteriaceae. The role of these organisms in this habitat is not yet settled, but they are all defined by depositing storage polymers intracellularly under aerobic conditions. *Tessaracoccus bendigoensis* stores polyphosphate and may thus participate in phosphate removal (Seviour et al., 2000).

Isolation and Maintenance

The difficulties encountered in the isolation of strain ACM 5119^T required the use of a micro-manipulator (Skerman, 1968). Pure cultures were obtained by streaking out colonies arising from manipulated cells several times onto fresh GS medium (Williams and Unz, 1985), incubated at 25°C. Cultivation is at 28°C. For chemotaxonomic analyses, cells are scraped from R-agar plates (Yamada and Komagata, 1972) after growth at 22°C for 2–3 weeks.

GS (Glucose Sulfide) Medium (DSMZ Medium 851)

Glucose	0.15 g
Yeast extract	1.00 g
(NH ₄) ₂ SO ₄	0.50 g
CaCO ₃	0.10 g
Ca(NO ₃) ₂	0.10 g
KCl	0.05 g
K ₂ PO ₄	0.05 g
MgSO ₄ · 7H ₂ O	0.05 g
Na ₂ S · 9H ₂ O	0.20 g
Vitamin solution (Medium 131)	10.00 ml
Distilled water	990.00 ml
Adjust pH to 7.3.	

Fig. 10. Morphology of *Tessaracoccus bendigoensis* ACM 5119^T. A) Cells as observed in activated sludge biomass. Bar = 10 μ m. B) Scanning electron micrograph showing the characteristic tetrad morphology. Bar = 2 μ m. (Reproduced with permission from R. J. Seviour; from Maszenan et al., 1999.)

Vitamin Solution (Medium 131)

Biotin	2.000 mg
Folic acid	2.000 mg
Pyridoxine-HCl	10.000 mg
Thiamine-HCl · 2H ₂ O	5.000 mg
Riboflavin	5.000 mg
Nicotinic acid	5.000 mg
Ca-pantothenate	5.000 mg
<i>p</i> -Aminobenzoic acid	1.000 mg
Vitamin B ₁₂	0.010 mg
Distilled water	1 liter

R (rich) Medium (DSMZ Medium 736)

Bacto peptone (Difco)	10.00 g
Yeast extract	5.00 g
Casamino acids (Difco)	5.00 g
Meat extract (Difco)	2.00 g
Malt extract (Difco)	5.00 g
Glycerol	2.00 g
MgSO ₄ · 7H ₂ O	1.00 g
Tween 80	0.05 g

Agar	20.00 g
Distilled water	1 liter
Adjust pH to 7.2.	

Storage is at -80°C in GS medium containing 20% glycerol (Maszenan et al., 1999b). Lyophilized cultures can be stored long term at 8°C .

Morphological and Cultural Characteristics

Colonies are beige, visible after 2–3 d incubation at 25°C . Cells are arranged in tetrads, as seen in large numbers in the activated sludge biomass (Fig. 10A). The diameter of the individual spherical cells ranges from 0.5 to 1.1 μm (Fig. 10B). The type strain grows between 20 and 37°C (optimally at 25°C) and at pH 6–9 (optimally at pH 7.5).

Physiological, Biochemical and Chemotaxonomic Properties

Cells were grown on GS agar at 25°C for 5 days, suspended in physiological saline to the turbidity standard recommended by the manufacturer, and plates were incubated at 25°C for 24 h. Chemotaxonomic properties (Table 3) were determined using methods as listed in Table 2. A detailed listing of properties is indicated in the species description (Maszenan et al., 1999b). Table 4 only lists those properties which have also been determined for the majority of phylogenetically related taxa.

Family Propionibacteriaceae: The Genus *Propionibacterium*

ERKO STACHEBRANDT, CECIL S. CUMMINS AND JOHN L. JOHNSON

The suborder Propionibacterineae is one of the ten suborders of the class Actinobacteria (Stackebrandt et al., 1997), containing the family Propionibacteriaceae Delwiche 1957, emend Rainey, Ward-Rainey and Stackebrandt 1997, with the genera *Propionibacterium* (Orla-Jensen, 1909), *Luteococcus* (Tamura et al., 1994), *Micro-lunatus* (Nakamura et al., 1995) and *Propion-iferax* (Yokota et al., 1994). Recently, four new genera have been added to the family, i.e., *Fried-manniella* (Schumann et al., 1997), *Tessaracoccus* (Maszenan et al., 1999), *Micropruina* (Shintani et al., 2000) and *Propionimicrobium* (Stackebrandt et al., 2002; Table 1). Members of the Propionibacteriaceae genera are either aerobic or facultative anaerobic, exhibit different morphologies, peptidoglycan types and variations, and have a wide range of DNA G+C content (53–73 mol%); however, with respect to chemo-taxonomic properties (such as the pattern of polyamines [Busse and Schumann, 1999], major menaquinones, and fatty acids), they appear rather homogeneous (see the chapter The Family Propionibacteriaceae: The Genera Fried-manniella, Luteococcus, Micro-lunatus, Micro-pruina, Propioniferax, Propionimicrobium and Tessarococcus in this Volume). The family contains two phylogenetic clades, one embracing members of *Propionibacterium*, the other embracing representatives of the other family members (Stackebrandt et al., 2002).

The intragenomic 16S rDNA differences, which separate the most unrelated species of *Propionibacterium* (90–94% similarity), are as low as those separating the other genera of the family. The phylogenetic and chemotaxonomic distinctness of *P. lymphophilum* (Dasen et al., 1998) led to its reclassification as the type species of a new genus *Propionimicrobium* (Stackebrandt et al., 2002). This species was originally described as “*Bacillus lymphophilus*” (Torrey 1916), “*Corynebacterium lymphophilum*” (Torrey 1916) Ebersson 1918 and “*Mycobacterium lymphophilum*” (Torrey 1916) Krasil’nikov 1949, and the type strain ATCC 27520^T was tentatively classified as *Propionibacterium lymphophilum*. A second *Propionibacterium* species that has

recently been excluded from this genus is *Propionibacterium innocuum* (Pitcher and Collins, 1991), now *Propioniferax innocua* (Yokota et al., 1994). The reclassification was based on phylogenetic position of the type strain which, in contrast to the descriptions of most *Propionibacterium* species (Cummins and Johnson, 1986; Charfreitag and Stackebrandt, 1988; Kusano et al., 1997), shows aerobic and facultatively anaerobic growth, contains arabinose in cell wall hydrolysates, and does not require blood, serum or Tween 80 for growth.

Three new species have recently been added to the genus. *Propionibacterium cyclohexanicum* has been isolated from spoiled fruit juice (Kusano et al., 1997), *P. australiense* from granulomatous bovine lesions (Bernard et al., 2002), and *P. microaerophilum* from olive mill wastewater (Koussémon et al., 2001).

The first systematic investigations into the organisms responsible for the formation of “eyes” in cheese were made by Von Freudenreich and Orla-Jensen (1906), although the earlier work of Fitz (Fitz, 1878; Fitz, 1879) had already shown that organisms from cheese would ferment lactate to propionic and acetic acids and liberate carbon dioxide in the process. The name “*Propionibacterium*” was suggested by Orla-Jensen (1909) for these organisms because they were characterized by the production of large amounts of propionic acid during growth. The economic importance of these organisms primarily derives from their role in the cheese industry. However, many of them also produce commercially valuable amounts of vitamin B₁₂ under suitable conditions, and they have also been used for the commercial production of propionic acid.

The strains originally classified in the genus all came from cheese or dairy products. Traditionally, the term “classical propionibacteria” has been used for these organisms. Later it has been shown that some of the so called “anaerobic coryneform organisms” that form a major part of the skin flora of humans share so many properties with the strains of dairy origin that it seemed justified to regard them also as members of *Propionibacterium*. Douglas and Gunter

Table 1. Validly published species in the family Propionibacteriaceae, the 16S rRNA gene accession number of the type strain, and the diagnostic amino acid of their peptidoglycan.

(1946) and Moore and Cato (1963) showed that propionic acid was a major end product of their metabolism. Subsequent work has shown that the anaerobic coryneforms from skin differ in several fundamental ways from the classical corynebacteria (e.g., *Corynebacterium diphtheriae*). For example, they do not produce mycolic acids, the diamino-acid of the cell wall peptidoglycan is not meso-diaminopimelic acid (A₂pm) but LL-A₂pm in almost all cases, and their cell wall polysaccharide does not contain arabinose (Johnson and Cummins, 1972; Rogosa et al., 1974). The term “cutaneous propionibacteria” refers to the organisms from skin, but only a few species are clinically significant. Recent reviews on these organisms were published by Brook and Frazier (1991), Eady and Ingham (1994), and Funke et al. (1997a).

The organisms in both groups are Gram-positive, diphtheroid, rod-shaped bacteria that may bifurcate or even branch; they are non-poreforming, nonmotile and anaerobic, though not strictly anaerobic but microaerophilic. The cutaneous propionibacteria, however, are generally slender and often quite irregular and curved, while the classical propionibacteria are usually

rather short and thick. Despite being predominantly anaerobic, propionibacteria are generally catalase positive, and in many cases strongly so.

A Historic View of Classical and Cutaneous Propionibacteria

Classical Propionibacteria

A number of investigators (Troili-Petersson, 1904; Von Freudenreich and Orla-Jensen, 1906; Thöni and Allemann, 1910; Sherman, 1921; Shaw and Sherman, 1923; Sherman and Shaw, 1923) described the isolation of different kinds of propionic acid bacteria from cheese, but Van Niel (1928) was the first to deal with the classification of these organisms in any systematic way. He reviewed the earlier work, described his own investigations, and recognized eight species, *Propionibacterium freudenreichii*, *Propionibacterium jensenii*, “*Propionibacterium peterssonii*,” *Propionibacterium shermanii*, “*Propionibacterium pentosaceum*,” “*Propionibacterium rubrum*,” *Propionibacterium thoenii* and “*Propionibacterium technicum*.” He also recognized

Propionibacterium jensenii var. *raffinosa* as a variety of *Propionibacterium jensenii*. Since van Niel's classic paper, a number of taxonomic studies have been done. Werkman and Kendall (1931) have redesignated the variety of *Propionibacterium jensenii* as a species, "*Propionibacterium raffinosa*," and Hitchner (1932) named two more species, "*Propionibacterium zeae*" and "*Propionibacterium arabinosum*." Sakaguchi et al. (1941) have proposed five additional species: *Propionibacterium globosum*, "*Propionibacterium amylaceum*," "*Propionibacterium japonicum*," "*Propionibacterium orientum*" and "*Propionibacterium coloratum*," with one variety of "*Propionibacterium amylaceum*," "*Propionibacterium amylaceum* var. *auranticum*." In addition, Janoschek (1944) named three more species, "*Propionibacterium casei*," "*Propionibacterium pituitosum*" and "*Propionibacterium sanguineum*."

Several authors (e.g., Van Niel, 1928; Werkman and Brown, 1933; Janoschek, 1944; Holdeman et al., 1977) have constructed keys for the differentiation of the species primarily on the basis of pigment production and fermentation of various carbohydrates. However, the total number of strains examined is rather small for many species, and the results of fermentation tests by different investigators do not always agree. Malik et al. (1968), using 38 morphological and physiological features to examine 56 strains, grouped the strains into four clusters by numerical taxonomy, and Johnson and Cummins (1972), using cell wall and DNA hybridization analysis on 29 strains, also found four groups that agree in many respects with those proposed by Malik and his colleagues. Table 2 gives the DNA similarity data of strains arranged in the DNA

similarity groups described by Johnson and Cummins (1972). The principal difference between this scheme and that of Malik et al. (1968) is in the disposition of strains of "*Propionibacterium rubrum*," which Malik found showed a rather low level of similarity with strains of *Propionibacterium thoenii*, whereas by homology they appear to be closely related. Baer (1987) has also found that four groups can be distinguished by electrophoresis of soluble proteins, and the groups correspond exactly with those found by DNA studies (Table 1).

The species described by Janoschek (1944) and Sakaguchi et al. (1941) appear to have been lost. Of Janoschek's three species, it seems likely from the original descriptions that "*Propionibacterium casei*" is closely related to *Propionibacterium freudenreichii*, while "*Propionibacterium pituitosum*" and "*Propionibacterium sanguineum*" fall into the *Propionibacterium thoenii* group. Of the five species described by Sakaguchi et al. (1941), "*Propionibacterium orientum*," "*Propionibacterium globosum*," and "*Propionibacterium coloratum*" are probably related to *Propionibacterium freudenreichii*, while "*Propionibacterium amylaceum*" and "*Propionibacterium japonicum*," which are nitrate negative but ferment sucrose and maltose, would probably fall into the *Propionibacterium jensenii* group.

In summary, all investigators seem to agree that strains of *Propionibacterium freudenreichii* and "*Propionibacterium shermanii*" and "*Propionibacterium globosum*" are closely related and should be included in a single species, *Propionibacterium freudenreichii*. Today, this move has been done by treating "*Propionibacterium shermanii*" and "*Propionibacterium globosum*" as subspecies of *Propionibacterium freudenreichii*.

Table 2. DNA-DNA a and DNA-rDNA b relatedness between *Propionibacterium* species (% DNA similarity).

^aFilter hybridization method; see Johnson and Cummins (1972).

^bMembrane filter hybridization assay using acetylaminofluorene-labelled rRNA as a probe; see de Carvalho et al. (1994).

^cNames in parentheses refer to invalid species. *Propionibacterium shermanii* is now a subspecies of *Propionibacterium freudenreichii*.

These strains also differ from the other classical propionibacteria in fermenting a more restricted range of carbohydrates, in being heat resistant (Malik et al., 1968), and in having a rather distinctive pattern of cell wall components (Table 1). Strains of "*Propionibacterium arabinosum*" and "*Propionibacterium pentosaceum*" are also closely related to each other, being the only strains in which catalase production is weak ("*Propionibacterium pentosaceum*") or absent ("*Propionibacterium arabinosum*"). They have therefore been placed into a single species, *Propionibacterium acidipropionici*. The two groups *Propionibacterium thoenii* and *Propionibacterium jensenii*, which show the highest degree of DNA similarity (51–53%; Table 2), also show a considerable range of phenotypic variation. The original species designations within these groups were based on various fermentation tests (Breed et al., 1957).

Fermentation patterns have been the basis of distinction between named strains in almost all identification schemes, and most authors (e.g., Van Niel, 1928; Werkman and Brown, 1933; Janoschek, 1944) have devised identification keys based on such tests. In the eighth edition of *Bergey's Manual* (Moore and Holdeman, 1974), the classical propionibacteria were classified in four species, *Propionibacterium freudenreichii* (with "*Propionibacterium shermanii*"), *Propionibacterium thoenii* (including "*Propionibacterium rubrum*"), *Propionibacterium jensenii* (including "*Propionibacterium zeae*," "*Propionibacterium technicum*," "*Propionibacterium raffinosum*" and "*Propionibacterium petersonii*"), and *Propionibacterium acidipropionici* (including "*Propionibacterium arabinosum*" and "*Propionibacterium pentosaceum*"), primarily on the basis of homology groupings, and the same scheme has been followed in the first edition of *Bergey's Manual of Systematic Bacteriology* (Cummins and Johnson, 1986).

A species of doubtful taxonomic status is the invalid "*Propionibacterium coccoides*." As described by Vorob'eva et al. (1983), these are Gram-positive, nonmotile, nonsporeforming organisms isolated from Russian cheese. The organisms are spherical at all stages of growth, are facultative anaerobes, growing well at 22–30°C (but also down to 8–10°C), and are halotolerant up to 6.5% NaCl. The G+C content is 63.4 mol% and they are reported to show 48% DNA sequence similarity to a strain of *Propionibacterium jensenii*. They are catalase positive, produce vitamin B₁₂ and ferment lactate with the production of propionate, acetate and CO₂ as principal end products, apparently by the succinate-methylmalonylCoA pathway. These organisms are reported to ferment a wide variety of carbohydrates, and this, along with their abil-

ity to grow at temperatures as low as 8–10°C, would appear to distinguish them from *Propionibacterium freudenreichii*, the cells of which also can often appear coccal.

Cutaneous Propionibacteria

Organisms in this group were regarded as belonging to the genus *Corynebacterium* until Douglas and Gunter (1946) and Moore and Cato (1963) showed that propionic acid was a major end product of their metabolism. Subsequent work has shown that the anaerobic coryneforms from skin differ in several fundamental ways from the classical corynebacteria (e.g., *Corynebacterium diphtheriae*). For example, they do not produce mycolic acids, the diamino-acid of the cell wall peptidoglycan is LL-A2pm in almost all cases, and their cell wall polysaccharide does not contain arabinose (Johnson and Cummins, 1972; Rogosa et al., 1974). At one time, as many as 12 species of anaerobic coryneforms were described (Prévot and Fredette, 1966). However, an examination of 80 strains by cell wall analysis and by DNA hybridization analysis showed only three major groups that seemed sufficiently distinct to be regarded as species (Johnson and Cummins, 1972). In *Propionibacterium acnes* and *Propionibacterium avidum*, two serotypes are found; these can be distinguished by precipitin tests using trichloroacetic acid extracts (Cummins, 1975). The three groups can also be recognized by the gel electrophoresis pattern of soluble proteins (Gross et al., 1978; Nordstrom, 1985). The organism generally referred to as *Corynebacterium parvum*, which causes an unusual degree of reticulostimulation and macrophage-activation in animals, was found to be indistinguishable from *Propionibacterium acnes* (Cummins and Johnson, 1974).

Most strains of *Propionibacterium acnes* and *Propionibacterium granulosum* grow poorly, if at all, under aerobic conditions, although they are not sensitive to oxygen and organisms will remain viable for several hours or longer if plate cultures are left exposed to air. Strains of *Propionibacterium avidum*, however, will grow quite well under aerobic conditions. The requirement to grow the organisms anaerobically has led to the phrase "anaerobic coryneforms" or "anaerobic corynebacteria." However, McGinley et al. (1978) have used the phrase "cutaneous propionibacteria," and this seems in many ways more appropriate because the skin does appear to be the main reservoir of these organisms.

In most cases, the major problem in identifying these organisms is one of distinguishing them from morphologically similar organisms also isolated from skin swabs or clinical specimens. All members of the group produce major amounts

of propionic and acetic acids as end products of hexose metabolism (generally about 2–3 moles of propionate for 1 mole of acetate), and this pattern can readily be established by gas chromatography of culture supernatants (Holdeman et al., 1977). Also, almost all strains contain the L-isomer of diaminopimelic acid (A_2pm) as the diamino-acid of peptidoglycan (Johnson and Cummins, 1972). Most morphologically similar groups, e.g., *Actinomyces israelii*, *Actinomyces naeslundii*, and aerobic skin diphtheroids resembling *Corynebacterium xerosis*, either do not have A_2pm (for example, *Actinomyces israelii*) or have the *meso* isomer (aerobic skin diphtheroids).

Strains of *Propionibacterium acnes* and *Propionibacterium granulosum* grow rather slowly on solid media, and, especially with *Propionibacterium acnes*, colonies may still be under 1 mm in diameter at 4 days. Colonies of *Propionibacterium granulosum* are generally a little larger and more creamy and opaque than those of *Propionibacterium acnes*. Strains of *Propionibacterium avidum* grow considerably faster than either of the other species and show good growth in 48 h.

On blood agar, many strains of *Propionibacterium acnes* and most strains of *Propionibacterium avidum* are β -hemolytic on human, rabbit, or horse blood (Hoeffler, 1977). However, except for *Propionibacterium avidum*, there is no hemolysis on sheep blood agar. Cummins and Johnson (1991) have found strains of *Propionibacterium granulosum* to be nonhemolytic, but Hoeffler (1977) reported them to be β -hemolytic on rabbit blood agar.

Habitat

The classical propionibacteria have been traditionally isolated from dairy products, especially cheese, and it appears that no systematic search has been made for them in other habitats. However, Van Niel (1957) reported that strains of “*Propionibacterium peterssonii*” had been isolated from soil and that “*Propionibacterium zae*” had been isolated from silage, but gave no further details. Prévot and Fredette (1966) said that “*Propionibacterium pentosaceum*” had been isolated from soil but gave no reference. Propionibacteria have also been reported from fermenting olives (Plastourgos and Vaughn, 1957; Cancho et al., 1970; Cancho et al., 1980) and from the soil of rice paddies (Hayashi and Furusaka, 1980). The non-dairy strains have been isolated from different habitats, i.e., *Propionibacterium cyclohexanicum* from pasteurized spoiled off-flavor orange juice in Japan (Kusano et al., 1997) and *P. microaerophilum* from a decantation reservoir of olive mill wastewater

of an olive oil factory in Southern France (Koussémon et al., 2001).

Propionibacteria are important in the development of flavor during the ripening process in the manufacture of Swiss cheese, especially the Emmental variety. The growth of propionibacteria during the “warm-room” period of cheese ripening (72–78°F) produces propionic acid and CO_2 from the lactate left by the earlier action of lactobacilli. The CO_2 is responsible for the “eyes” or gas vacuoles characteristic of such cheeses, while the propionic acid, and probably also proline and other amino acids, is important in the flavor (Langsrud and Reinbold, 1973a; Langsrud and Reinbold, 1973b; Langsrud and Reinbold, 1973c; Langsrud and Reinbold, 1973d). The starter cultures of propionibacteria used in cheese manufacture are usually described as *Propionibacterium freudenreichii* subsp. *freudenreichii* or subsp. *shermanii*, and these strains appear to be the most important for flavor. Strains of other species are present in relatively small numbers.

In Emmental-type cheese made in Finland, Meriläinen and Antila (1976) found that over 60% of the strains isolated could be described as *Propionibacterium freudenreichii* subsp. *freudenreichii* or subsp. *shermanii*. They isolated no strains that they could identify as *Propionibacterium thoenii*, and apparently these highly pigmented strains only occur as undesirable contaminants in cheese making (Langsrud and Reinbold, 1973d).

Cutaneous propionibacteria, then classified as coryneform organisms, were first observed in material from *acne comedones* (the lesions of the disease *acne vulgaris*) by Unna (1893) and were cultured from the lesions by Sabouraud (1897). It was assumed that these organisms were the cause of acne until 1911, when Lovejoy and Hastings (1911) isolated an apparently identical organism from the skin of persons without acne; since then, the relationship between the acne bacillus and the lesions of acne has been a matter of continued debate. The distribution of the various species of cutaneous propionibacteria on the human body has been investigated by McGinley et al. (1978). *Propionibacterium acnes* is the predominant organism, especially in areas rich in sebaceous glands such as the forehead and the naso-labial folds. *Propionibacterium granulosum* is the next most common and has a similar distribution to *Propionibacterium acnes*, except that it is especially common in the alae nasi region (wing of the nose). *Propionibacterium avidum* has a more restricted distribution and is found mostly in moist rather than oily regions, such as the axilla, perineum, or anterior nares. Organisms of this group have also been isolated from the mouth, the female genital tract, and

from feces. They are also common contaminants in anaerobic cultures, probably coming from the skin of the operator during subculture.

Phylogeny

The first phylogenetic study on 16S rDNA catalogues showed *Propionibacterium freudenreichii* and *Propionibacterium acnes* to form a separate line of descent within the order Actinomycetales (Stackebrandt and Woese, 1981). Comparison of almost complete 16S rDNA sequences of these two species, *Actinomyces* species, and *Arachnia propionica* led to the reclassification of the latter species as *Propionibacterium [propionicus] propionicum* (Charfreitag and Stackebrandt, 1988). More comprehensive studies on the genus followed (Charfreitag and Stackebrandt, 1989; Dasen et al., 1998), and the 16S rDNA of all type strains has by now been completed (Kusano et al., 1997; Koussémon et al., 2001; Bernard et al., 2002). Strains isolated from dairy sources are *Propionibacterium freudenreichii*, *Propionibacterium acidipropionici*, *Propionibacterium microaerophilum*, *Propionibacterium jensenii* (rare humans), and *Propionibacterium thoenii*. The latter four species cluster apart from strains isolated from human skin, viz., *Propionibacterium acnes*, *Propionibacterium avidum* and *Propionibacterium granulosum*. *Propionibacterium freudenreichii*, on the other hand, forms a loose phylogenetic cluster with two non-dairy organisms, i.e., *Propionibacterium cyclohexanicum* (from spoiled orange juice) and *Propionibacterium australiense* (from bovine lesions). Thus, the traditional separation of *Propionibacterium* into dairy propionibacteria and the cutaneous propi-

onibacteria is not fully matched by their phylogenetic relationships.

Different studies agree on the topology of trees with the exception of the position of *Propionibacterium propionicum*: in the study of Charfreitag and Stackebrandt (1989), the type strain DSM 43307^T (accession number X53216) clusters distantly from *Propionibacterium acnes*, but as depicted in Fig. 1, clusters outside the main *Propionibacterium* cluster, next to *Tessarococcus bendigoensis*. The isolated position of *Propionibacterium propionicum* was also confirmed by Kusano et al. (1997), and the sequence was also obtained from a *Propionibacterium propionicus* strain VA1535 isolated from a patient with canaliculitis (unpublished observation of W. Geissdoerfer et al.; accession number AF285117). In contrast, a new sequence of strain DSM 43307^T obtained by Dasen et al. (1998) showed this species to be closely related to *Propionibacterium acnes* and *Propionibacterium avidum*. Similarly, Koussémon et al. (2001) and Bernard et al. (2002) showed *Propionibacterium propionicum* (with the accession numbers X53216 and AJ003058, respectively) to be related to *Propionibacterium avidum* and *Propionibacterium acnes*. To solve this problem, a new strain of DSM 43307^T was sequenced for this communication and the result of Charfreitag and Stackebrandt (1989) was confirmed. Obviously, more than a single, genetically defined type strain is in use in different laboratories and this problem should be solved before *Propionibacterium propionicum* can be excluded from the genus *Propionibacterium*.

Nucleic acid reassociation studies have been performed to verify the species status (Johnson and Cummins, 1972), to affiliate strains to

Fig. 1. Distance matrix analysis (De Soete, 1983) of almost complete 16S rDNA sequences of species of the family Propionibacteriaceae. Numbers refer to bootstrap values (500 resamplings). Names in red: cutaneous propionibacteria; names in blue: classical propionibacteria.

described species (De Carvalho et al., 1994; Table 3), and to monitor the existence of propionibacteria in natural samples (Sunde et al., 2000). The studies on described species revealed the genomic distinctness of *Propionibacterium freudenreichii*, *Propionibacterium acidipropionici*, *Propionibacterium thoenii* and *Propionibacterium jensenii* (Table 2), of *Propionibacterium acnes*, *Propionibacterium avidum* and *Propionibacterium granulosum* (Table 3), as well as that of *Propionibacterium acidurici* and *P. microaerophilum* (56% DNA reassociation; Koussémon et al., 2001). A DNA array-like "checkerboard" DNA-DNA hybridization technique has been performed to identify *Propionibacterium acnes* in periapical endodontic lesions of asymptomatic teeth. The occurrence of members of these species was verified in marginal and submarginal incision performed to expose the lesion, though the frequency of bacteria and their concentration of *P. acnes* varied significantly in these two types of incisions (Sunde et al., 2000).

Molecular Identification

To reliably identify prokaryotic organisms, molecular identification systems have been developed during the past decade. Derived from the suitability of ribosomal RNA genes to unravel phylogenetic relationships, methods were applied to rapidly identify *Propionibacterium* strains. These techniques were used to affiliate strains to named species and to identify strains directly in environmental samples. Approaches are based on restriction fragment analysis of total DNA (Gauthier et al., 1996), restriction analysis of amplified 16S rDNA (Riedel et al., 1998; Hall et al., 2001), or on polymerase chain reaction (PCR) assays targeting 16S rDNA (Dasen et al., 1998). One of the earliest studies used manual rRNA gene restriction patterns (riboprinting; Grimont and Grimont, 1986; De Carvalho et al., 1994; Riedel et al., 1994). These patterns are obtained by cleavage of total DNA with restriction endonucleases,

one-dimensional separation of DNA fragments, and hybridization of fragments with labeled 16+23S rRNA from *Escherichia coli*. Today this method is provided by an automated system (Dupont, Wilmington, DE, United States). In the study of De Carvalho et al. (1994), the six species analyzed with *Cla*I, i.e., *Propionibacterium freudenreichii*, *Propionibacterium jensenii*, *Propionibacterium thoenii*, *Propionibacterium acnes*, *Propionibacterium propionicum* and *Propionibacterium acidipropionici*, gave different restriction patterns, consisting of two to four bands; the method was sensitive enough to even discriminate between the two subspecies of *Propionibacterium freudenreichii*, i.e., subsp. *freudenreichii* and subsp. *shermanii*. Culture collection strains affiliated to certain species were often found to be misidentified, belonging to different described species, or even to represent novel taxonomic entities. Another study applied randomly amplified polymorphic DNA (RAPD) PCR (Rossi et al., 1998; Langsrud and Reinbold, 1973a).

Alternatively, ribosomal RNA genes are amplified, using a combination of conserved and *Propionibacterium*-specific oligonucleotide primers (e.g., primer *gd1* in a multiplex-PCR; Dasen et al., 1998). The use of the latter probe resulted in the formation of a 900-bp long fragment, identifying members of *Propionibacterium*, whereas members of other genera, lacking the *Propionibacterium*-specific target site of the *gd1* primer, yielded a 1500-bp amplificate. The assay can be performed within 1 day and the detection limit is about 10³ colony forming units (cfu) of propionibacteria. The study of Rossi et al. (1999) used different primer sets for *Propionibacterium acnes* and *Propionibacterium* species occurring most frequently in raw milk. The target sites for these primers were located between positions 435 and 478 (*E. coli* nomenclature) of the 16S rDNA. The test allowed the detection of less than 10 cells per PCR assay from milk and cheese and 10² cells per PCR assay from forage and soil. Greisen et al. (1994) used a different target stretch (pos. 1376–1400 of the 16S rDNA); all of the four *Propionibacterium* species but

none of the Gram-positive and Gram-negative reference strains of clinical significance tested positive. Nested 16S rDNA primers were used to identify *Propionibacterium propionicum* in patients with primary and persistent endodontic infections (Siqueira and Rocas, 2003).

Strains of several *Propionibacterium* species were included as references in a study by Kaufmann et al. (1997) in which a 16S rDNA-targeted probe directed against species of *Bifidobacterium* was evaluated by colony hybridization. Of all the *Propionibacterium* references tested, *Propionibacterium freudenreichii* subsp. *shermanii* gave a slight signal. This is surprising as the target stretch is identical in all propionibacterial 16S rDNAs analyzed.

Random amplification of polymorphic DNA (RAPD) was used in epidemiological studies of *P. acnes*, in the discrimination of *Propionibacterium acnes* strains from *Propionibacterium granulosum* and *Propionibacterium avidum* (Perry et al., 2003), and in the identification of dairy propionibacteria (Rossi et al., 1999). The discrimination power of the arbitrary primed PCR (AP-PCR) approach was lower than that of the pulsed-field gel electrophoresis approach (Jenkins et al., 2002), and the authors concluded that *Propionibacterium freudenreichii* strains used for Swiss cheese production in the United States were genetically diverse.

Pulsed-field gel electrophoresis has been used for strain typing of staphylococci and propionibacteria to the discriminate primary pathogens causing inflammatory reactions following cardiac surgery (Tammelin et al., 2002). Molecular identification of as yet uncultured and cultured microorganisms including propionibacteria followed the widely applied cloning and sequence analysis of PCR amplified 16S rDNA genes.

Clinical samples investigated included endodontic infections (Rolph et al., 2001) and noma lesions (Paster et al., 2002), demonstrating the presence of *P. acnes*. The two types of *P. acnes* (I and II) could be discriminated on the basis of the two dimensional separation patterns of ribosomal proteins, though the differences were small as compared to those between *Propionibacterium acnes* and *Propionibacterium granulosum* (5 versus 50 proteins; Dekio et al., 1989).

Phenotypic Properties

A compilation of tests differentiating species in the genus *Propionibacterium* is given in Tables 4 and 5. While the information is based on the analyses of many strains originating from skin, human flora or dairy sources, only six strains are available for *Propionibacterium australiense*, while the species *Propionibacterium microaerophilum* and *Propionibacterium cyclohexanicum* are represented only by their type strain.

Several studies on the evaluation of commercial identification kits have included strains of *Propionibacterium* species, but the number of strains and species was generally low. Comparing the results obtained by methods described by the Virginia Polytechnic Institute and State University with results obtained by the RapID-ANAI system (Innovative Diagnostic Systems, Inc., Atlanta, GA, United States) the latter system performed well in that 91% of the 23 strains of *P. acnes* were correctly identified (Celig and Schreckenberger, 1991). Similarly, the ATB 32A system (API System SA, Montalieu-Vercieu, France) correctly identified 100% of the 10 strains of *P. acnes* when compared to conventional identification methods (Looney et al., 1990). Also satisfying were the results obtained

with the BBL Crystal Anaerobe (ANR, Becton Dickinson) identification system in that 26 strains of *Propionibacterium acnes*, *Propionibacterium avidum* and *Propionibacterium granulosum* were correctly identified (Cavallaro et al., 1997). In contrast, identification problems were reported to occur for *Propionibacterium acnes* and *Propionibacterium avidum*, using the API (RAPID) Coryne System with database 2.0 (bioMérieux, La-Balme-les-Grottes, France; Funke et al., 1997b). *Propioniferax innocua*, not included in the API Coryne database 2.0, was identified as *Brevibacterium epidermidis* or *casei*.

Fluorogenic 4-methylumbelliferyl-linked substrate tests have been applied to rapid characterization of periodontal bacterial isolates, tested against reference strains. The type strains of *Propionibacterium avidum*, *Propionibacterium granulosum*, *Propionibacterium propionicum* and *Propionibacterium acnes* gave characteristic profiles but the patterns obtained from fresh isolates differed to some extent from those of the type strains (Maiden et al., 1996).

An alternative rapid identification method not based on physiological properties is pyrolysis mass spectrometry (PyMS). The spectra obtained from reference *Propionibacterium* strains and isolates were used to train artificial neural networks (Goodacre et al., 1994), which were able to recognize strains from dogs as human wild type *P. acnes*. In a later study (Goodacre et al., 1996), strains of *P. acnes* isolated from the forehead of healthy humans could be differentiated. Biochemical characteristics in combination with PyMS revealed the significant differences among the strains, some of which occurred simultaneously in the same habitat.

Fig. 2. Propionic acid fermentation and the formation of acetate, CO₂, propionate and ATP. FP, flavoprotein; FPH₂, reduced flavoprotein.

General Properties

Metabolism and Nutritional Requirements

The production of large amounts of propionic acid is characteristic of the propionibacteria. Hexoses are converted to pyruvate by the Embden-Meyerhof pathway, and propionate and acetate are formed by the reactions shown in Fig. 2. This diagram of propionic acid fermentation is slightly modified from that given by Allen et al. (1964) and is based on the extensive work of H. G. Wood and his collaborators (for references, see Allen et al., 1964). The background to propionic acid fermentations is also critically dis-

cussed in the reviews by Hettinga and Reinbold (Hettinga and Reinbold, 1972a; Hettinga and Reinbold, 1972b; Hettinga and Reinbold, 1972c). The fact that propionic and acetic acids are the main products of hexose fermentation can be readily shown by gas chromatography of culture supernatants (for methods, see Holdeman et al., 1977). The ratio of propionic to acetic acid is generally about 2 : 1 but may vary widely and be as high as 5 : 1 or more. Lactic acid is produced in addition to propionic acid and acetic acid by strains of *Propionibacterium cyclohexanicum* and *Propionibacterium propionicum*. The latter species, as well as *Propionibacterium australiense*, form also succinic acid (Kusano et al., 1997; Bernhard et al., 2002).

The nutritional requirements for all propionibacteria are basically very similar, which suggests a close resemblance between the overall metabolisms of the two (the classical and the cutaneous) groups. All strains require the vitamins pantothenate and biotin (Delwiche, 1949); some need thiamine and *p*-aminobenzoic acid as well. A number of other unknown factors in potato and yeast extract are stimulatory for growth. It appears from the investigations of Wood et al. (1938) that many strains of propionibacteria will grow in a basal medium without the addition of amino acids. However, growth is much improved when amino acids are added: a digest of casein (e.g., casamino acids [Difco, Detroit, MI, United States]) will supply the requirements of all strains. Strains of *Propionibacterium acnes* require pantothenate, biotin, thiamine and nicotinamide. Strains of *Propionibacterium avidum* and *Propionibacterium granulosum* require pantothenate, biotin and thiamine only. Most strains need a full complement of 18 amino acids for good growth, and growth is further improved by the addition of 0.1–0.2% lactate, pyruvate and ketoglutarate and of guanine and adenine (Ferguson and Cummins, 1978).

Antigens

The polysaccharides of the walls of the classical propionibacteria can be extracted with trichloroacetic acid and give good immunoprecipitation reactions with antisera prepared against suspensions of whole cells (C. S. Cummins and P. Hall, unpublished observations). All polysaccharides except those from *Propionibacterium freudenreichii* contain 2, 3-diaminohexuronic acid (Cummins and White, 1983; Cummins, 1985).

A number of strains of cutaneous propionibacteria give suspensions that are unstable in saline and so are unsuitable for agglutination tests using suspensions of whole cells. However, antisera are commercially available (Difco, Detroit, MI, United States) that can be used for the iden-

tification of *Propionibacterium acnes* by the slide agglutination test. A clearer separation of the three species *Propionibacterium acnes*, *Propionibacterium granulosum* and *Propionibacterium avidum* and of their serotypes can be obtained by using cell wall polysaccharide antigens extracted from the cells by 10% trichloroacetic acid at 56°C (Cummins, 1975). A number of strains of *Propionibacterium avidum* are heavily capsulated (C. S. Cummins et al., unpublished observations), and it has been found that better antisera to cell wall antigens are produced if non-capsulated strains are used for immunization.

Sensitivity to Muralytic Enzymes

The intact cells and the isolated cell walls of the propionibacteria are lysozyme resistant (unless acetylated), except for the isolated cell walls of *Propionibacterium freudenreichii*, which are sensitive (C. S. Cummins, unpublished observation). However, all propionibacteria are moderately sensitive to some other muralytic enzymes, such as mutanolysin or achromopeptidase.

Bacteriophages

The bacteriophages of classical propionibacteria do not appear to have been investigated, although Hettinga and Reinbold (1972c) reported failure to isolate bacteriophage from their strains. They ascribed their failure to interference by slime layers.

A number of bacteriophage types have been described for *Propionibacterium acnes* (e.g., Prévot and Thouvenot, 1961; Jong et al., 1975; Webster and Cummins, 1978). Bacteriophages for *Propionibacterium avidum* and *Propionibacterium granulosum* have not been investigated; however, strains of these two species are not lysed by any of the *Propionibacterium acnes* phages. Some phage strains, e.g., strain 174 of Zierdt et al. (1968), will lyse most strains of *Propionibacterium acnes* and can be used for rapid presumptive species identification. Bacteriophages active against *Propionibacterium acnes* can readily be detected in filtrates of skin washings (Marples, 1974).

Propionocins

Few bacteriocins have been described among dairy propionibacteria active against Gram-positive and Gram-negative bacteria, yeasts and molds (Lyon and Glatz, 1993; Faye et al., 2000; Faye et al., 2002; Ben-Shushan et al., 2003; Gollop et al., 2003). These propionocins may include protease-activated antibacterial peptides. The propionocin SM1 from *Propionibacterium jensenii* DF1 shows strong bacteriocidal action against

Propionibacterium jensenii DSM 20274. The gene is located on a plasmid and the propionic amino acid sequence shows significant homologies to a protein excreted from *Lactobacillus lactis* (Miescher et al., 2000). Horizontal gene transfer could explain the presence in one but not in a second strain of the same species.

A mixture of *Propionibacterium jensenii* SM11 and different strains of *Lactobacillus paracasei* subsp. *paracasei* showed inhibitory activities against spoilage yeasts in dairy products at refrigerator temperature (Schwenninger and Meile, 2004).

Probiotics and Growth Stimulators

Growth stimulators for bifidobacteria were found in culture broth of *Propionibacterium freudenreichii* (Isawa et al., 2002); Isawa et al. (2002) identified one stimulator as 1,4-hydroxy-2-naphthoic acid, while Mori et al. (2000) identified another factor as 2-amino-3-carboxy-1,4-naphthoquinone. Also, short-chain fatty acids, such as propionate, stimulated the growth of bifidobacteria while being highly inhibitory to the growth of Gram-negative facultative and obligatory anaerobes (Kaneko et al., 1994).

Chemotaxonomic Properties

In contrast to most other genera of the class Actinobacteria, members of *Propionibacterium* exhibit different peptidoglycan types. The diamino acid of peptidoglycan is meso-A₂pm (type A1γ), LL-A₂pm (type A3γ) or a combination of both amino acids (Schleifer and Kandler, 1972; Kusano et al., 1997; Table 1). Other distinctive wall components are sugars composed of mainly glucose, mannose and rhamnose. Galactose may be present. Kusano et al. (1997) display chemotaxonomic data of all *Propionibacterium* species described until 1997. The major menaquinone is MK-9(H₄) (a quinone with 4 hydrogen atoms on the side chain containing 9 isoprene units) and the mol% G+C of DNA is 57–68. The fatty acid profiles are dominated by branched acids (C_{15:0} or C_{a15:0} or both) while straight chain fatty acids (C_{15:0}, C_{16:0}, and C_{17:0}) occur in significantly lower amounts (Moss et al., 1969; Cummins and Moss, 1990; Bernard et al., 1991; Bernard et al., 2002). ω-Cyclohexyl undecanoic acid is the major fatty acid compound in *Propionibacterium cyclohexanicum* (57%; Kusano et al., 1997). The most comprehensive compilation of fatty acid data is presented by Bernard et al. (2002), which however omits data of *Propionibacterium cyclohexanicum*. Mannose-containing phospholipids have been reported in *Propionibacterium freudenreichii* subsp. *shermanii* (Brennan and Ballou,

1968; Prottey and Ballou, 1968). Complex lipids that have chemoattractant properties for phagocytes have been extracted from strains of *Propionibacterium acnes* (Russel et al., 1976).

Hettinga and Reinbold (1972c), quoting unpublished work by Skogen (1970), reported that a strain of *Propionibacterium jensenii* (“*Propionibacterium zeae*”) produced slime and capsular material composed of glucose and galactose. Cummins and Johnson (1991) report that a number of strains of *Propionibacterium thoenii* and *Propionibacterium jensenii* are capsulated (C. S. Cummins and P. Hall, unpublished observations), as have Skogen et al. (1974), and a number of species produce extracellular slime that makes cultures in liquid medium quite viscous. The capsular material is polysaccharide.

Sensitivity to Antimicrobial Agents

No very consistent or unusual pattern has been reported, except that all strains are highly resistant to sulfonamides and appear to be more resistant to semisynthetic penicillins (such as oxacillin) than to penicillin G (Reddy et al., 1973a). When disk sensitivity tests are used, some strains will grow in the presence of 1000 µg/ml sulfadiazine. Reddy et al. (1973b) have shown that some subspecies of *Propionibacterium freudenreichii* and *Propionibacterium thoenii* and some strains of *Propionibacterium acidipropionici* can synthesize folic acid, while other strains of *Propionibacterium acidipropionici*, *Propionibacterium thoenii* and *Propionibacterium jensenii* cannot. However, the latter strains are still resistant to sulfonamides, and Reddy et al. (1973a) concluded that this resistance may be due to the failure of the drugs to enter the cell. Among other antimicrobial substances, nisin (from streptococci) has an inhibitory effect on the growth of propionibacteria in Emmental cheese (Gale-sloot, 1957; Winkler and Fröhlich, 1957).

Strains of *Propionibacterium acnes* were found to be sensitive to penicillin, erythromycin, tetracyclines, chloramphenicol and novobiocin and resistant to streptomycin and sulfonamides (Pochi and Strauss, 1961). The strains were particularly resistant to sulfonamides and would grow in the presence of concentrations of more than 500 µg/ml.

Isolation and Maintenance

Classical Strains

Most investigators from Van Niel (1928) onward have relied primarily on yeast extract-sodium lactate media, with or without the addition of peptone. A typical formula is that of Malik et al. (1968).

Yeast Extract-Sodium Lactate (YEL) Medium for Isolation and Maintenance of *Propionibacteria* (Malik et al., 1968)

Trypticase (BBL)	1%
Yeast extract (Difco)	1%
Sodium lactate	1%
KH ₂ PO ₄	0.25%
MnSO ₄	0.0005%
Agar (Difco)	1.5%

Dilute and dissolve in distilled water up to 1 liter and adjust the pH to 7.0.

Hettinga et al. (1968) have devised a method whereby 2% lactate agar is placed in a pouch made of a plastic film of low gaseous diffusibility to maintain sufficiently anaerobic conditions.

Media of this type have been used both for isolation and for the maintenance of stock cultures. Sufficiently anaerobic conditions were maintained by agar overlay (Malik et al., 1968), by the addition of 0.5% sodium sulfite coupled with an overlay of paraffin oil (Demeter and Janoschek, 1941), or by growth in candle oats jars (Vedamuthu and Reinbold, 1967). Probably the easiest method of isolation is to supplement the medium of Malik et al. (1968) with 0.05% cysteine and 0.05% Tween 80 and to incubate the plates in a Brewer-type anaerobe jar containing 10–20% CO₂. Chopped-meat medium in stoppered tubes under CO₂ (Holdeman et al., 1977) is excellent for preserving stock cultures. Cultures remain viable for many months at room temperature, but at refrigerator temperatures (e.g., 4°C), cultures may die out rather rapidly. For stock cultures, it is better to omit glucose from the medium.

Larger cultures for biochemical or cellular analysis may conveniently be grown in Erlenmeyer flasks by the method described by Cummins and Johnson (1971) and explained in detail by Cummins and Johnson (1991).

A medium supporting good growth of all the species of *propionibacteria* is as follows:

Trypticase-Yeast Extract-Glucose Medium for Growth of *Propionibacteria* (Johnson and Cummins, 1972)

Trypticase (BBL)	1%
Yeast extract (Difco)	0.5%
Glucose	1%
CaCl ₂	0.002%
MgSO ₄	0.002%
NaCl	0.002%
Potassium phosphate buffer	0.05 M
Tween 80	0.05%
NaHSO ₂ · CH ₂ O · 2H ₂ O (Eastman Organic Chemicals)	0.05%
NaHCO ₃	0.1%

Dissolve and dilute ingredients in 0.5 M potassium phosphate (equal molar mono- and dibasic), add NaHCO₃ as a sterile solution at the time of inoculation, and adjust pH to 7.0.

Completely synthetic media for the growth of *propionibacteria* have been devised by Kurmann (1960) and Reddy et al. (1973a).

Cutaneous Strains

Anaerobic coryneforms from the skin or other epithelial surfaces are easily obtained by swabbing suitable areas. Other methods of sampling are scraping with a sterile scalpel blade (Evans et al., 1950) or with the edge of a Teflon stirrer. The technique of Williamson and Kligman (1965), although originally designed for aerobes, is also very satisfactory for isolating *Propionibacterium acnes* or similar organisms from the skin surface, provided that anaerobic conditions are employed for cultivation. (The method is given in its original form below.)

Isolation of Anaerobic Coryneforms from the Skin (Williamson and Kligman, 1965)

1. Scrub the area (3.8 cm²), which is delineated by a sterile glass cylinder held firmly to the skin by two attached handles.
2. Pipet 1 ml of wash solution—0.1% Triton X-100 in 0.075 M phosphate buffer, pH 7.9—and scrub the area with moderate pressure for 1 min using a sterile Teflon stirrer.
3. Aspirate the wash fluid, replace it with a fresh 1-ml aliquot, and scrub again.
4. Pool the two washes and dilute an aliquot in 10-fold steps using 0.05% Triton X-100 in 0.0375 M phosphate buffer as diluent to prevent any reaggregation of organisms.
5. Plate the appropriate dilutions (usually 10⁰, 10⁻¹, 10⁻² for normal skin; 10⁻³ and 10⁻⁴ for areas of high bacterial density) in 15–20 ml of tryptic soy agar per plate.
6. After 48 h incubation at 37°C, count colonies and calculate viable cells in the original sample by standard methods.

Using this method, suitable media for anaerobic coryneforms are blood agar and peptone-yeast extract-glucose agar, pH 6.5, containing 0.1% Tween 80 (see also Kishishita et al., 1980). The plates need to be incubated anaerobically (e.g., GasPak jars containing H₂ and CO₂) for up to 7 days. Remember that strains of *Propionibacterium avidum* will frequently grow aerobically, although more slowly than on anaerobic plates.

This technique calls for special glass cylinders that can be held against the skin to contain fluid. However, satisfactory results can be obtained using swabs dipped in the detergent-buffer mixture and then squeezed to expel excess fluid. After sampling, the liquid in the swab is squeezed out into a measured volume of fluid to wash out organisms that have been picked up. Considerable variation in bacterial numbers is

found from person to person (Evans et al., 1950), and it is important to plate out several dilutions, as described in the preceding procedure of Williamson and Kligman (1965).

A detailed comparison of the results from scraping versus those from swabbing is given in Evans and Stevens (1976). Scraping is more likely to yield organisms from the pilosebaceous glands, while swabbing picks up surface organisms only.

The method for bulk culturing described for the classical propionibacteria is also applicable for growing the cutaneous propionibacteria.

Pathogenic Cutaneous Propionibacteria

As summarized by Funke et al. (1997a), the predisposing conditions for *Propionibacterium acnes*, *Propionibacterium avidum* and *Propionibacterium granulosum* are the presence of foreign bodies (prosthetic valves or prosthetic joints), immunosuppression, preceding surgery trauma, diabetes, and obstruction of sinus ostia. These species have also been identified to cause endophthalmitis (Hykin et al., 1994), brain abscesses, meningitis, arthritis, osteomyelitis, endocarditis and infections of the central nervous system (literature summarized by Funke et al., 1997a). Incubation times may last from a few days up to 12 months, even 18 months (Barazi et al., 1995). Using the decrease in mitochondrial dehydrogenase activity of *Propionibacterium acnes*-infected viable HeLa and fibroblastic cell cultures as a measure of cytotoxicity, the bacteria under anaerobic conditions could be shown to produce cytotoxic effects for as long as 8 months (Csukas et al., 2004). Funke et al. (1997a) observed that the clinical significance is inversely proportional to the time of appearance in culture, unless the patient has been pretreated with antibiotics. Propionibacteria are rarely killed but are susceptible to a broad range of antibiotics. No differences were detected in the effects of 11 antibiotics between *Propionibacterium acnes* serotypes I and II (Kishishita et al., 1980).

Retinaldehyde has been used to significantly decrease the counts of viable *Propionibacterium acnes* suggesting that a daily total application of 0.05% retinaldehyde exerts antibacterial activity (Pechere et al., 1999). Likewise, concomitant application of 5% (w/w) benzoyl peroxide together with 3% (w/w) erythromycin was shown to bring about significant reductions in acne grade and lesion counts caused by erythromycin-resistant propionibacteria (Eady et al., 1996).

Propionibacterium acnes

Because it is widely distributed on the skin of man, *Propionibacterium acnes* is a common contaminant in clinical specimens sent for bacteriological examination, and strains of this species were isolated eight times more frequently than other *Propionibacterium* species (Funke et al., 1997a). However, occasionally it may be isolated in circumstances where it appears clearly to be a primary pathogen, for example in septic arthritis (Yocum et al., 1982) and in endocarditis (Felner and Dowell, 1970; Wilson et al., 1972). It has also been claimed that variant strains of *Propionibacterium acnes*, transmitted by house dust mites, are implicated in the causation of Kawasaki disease, an acute febrile illness in children, which may be accompanied by coronary arteritis (Kato et al., 1983).

The relationship of *Propionibacterium acnes* to the disease acne vulgaris is obscure. The essential lesion in acne is plugging of the orifice of the sebaceous glands, and overgrowth of *Propionibacterium acnes* (and *Propionibacterium granulosum*) in the obstructed gland may produce sufficient acid to irritate the tissues, or soluble antigens leaking out of the gland may cause an inflammatory reaction. Severe inflammation and scarring in acne are almost always due to an associated staphylococcal infection. Especially biotype 3 (B3) strains, showing higher lipase activity than those of B1, B2 and B4, were isolated from severe skin rashes (Higaki et al., 2000). The lipase activity of *P. acnes* B3 strains was found to be higher than that of *Propionibacterium granulosum* (Higaki et al., 2001).

RETICULOSTIMULATORY PROPERTIES OF *PROPIONIBACTERIUM ACNES* In 1966 it was shown that killed suspensions of an organism called "*Corynebacterium parvum*" could prevent the development of tumors from inocula of malignant cells in syngeneic mice (Halpern et al., 1966; Woodruff and Boak, 1966). Suspensions of this and other similar strains were known to increase the rate of clearance of carbon particles from the blood stream and cause considerable hepatosplenomegaly in mice and other animals. The majority of strains of "*Corynebacterium parvum*" were later identified as *Propionibacterium acnes*, and almost all the remainder were *Propionibacterium avidum*.

Vaccines from strains of *Propionibacterium acnes* and *Propionibacterium avidum* generally produce considerable hepatosplenomegaly (although some strains are inactive), while strains of *Propionibacterium granulosum* do not. However, suspensions of *Propionibacterium granulosum* may be active in preventing tumor development (see Cummins, 1984). The exact

basis for the reticulostimulatory activity of these strains has not yet been established.

No statistically significant effect was found in the reduction of *Staphylococcus aureus* in quarter milk samples from untreated *Staphylococcus aureus*-infected lactating cows, *Staphylococcus aureus*-infected lactating cows treated with killed preparations of the putative immunostimulant *Propionibacterium acnes*, and untreated control (uninfected) cows (Dinsmore et al., 1995).

Propionibacterium avidum

This organism may be found in chronic infected sinuses, ulcers, abscesses, etc., but it usually is in combination with other organisms. Other than its occurrence in acne pustules, *Propionibacterium granulosum* has not been reported in pathological conditions.

Prophylactic application of *Propionibacterium avidum* KP-40 has been investigated in several studies for its immunostimulating effect in mice and swine. After application of this strain in combination with heparin to mice, the number of syngeneic sarcoma L-1 lung and liver tumor nodules decreased significantly (Beuth et al., 1987). Strain KP-40 is a potent stimulator of the macrophage-monocyte system and inducer of interferon as shown in comparative studies on vaccinated swine infected with classical swine fever virus and bacterial infectious agents such as *Haemophilus pleuropneumoniae* or *Erysipelothrix rhusiopathiae* (Markowska-Daniel et al., 1992; Markowska-Daniel et al., 1993a; Markowska-Daniel et al., 1993b).

Propionibacterium propionicum

The organism appears to be a normal inhabitant of the human mouth and can be isolated from dental plaque but may also cause canaliculitis and dacryocystitis. It has also been demonstrated in cervico-vaginal smears by fluorescent antibody techniques. Like *Actinomyces israelii*, it may be found in the lacrimal duct as a cause of lacrimal canaliculitis, and in typical actinomycosis involving the cervico-facial area and occasionally elsewhere (Brock et al., 1973; Edminton, 1991). *Propionibacterium propionicum* was differentiated from *Propionibacterium acnes* by analyses of thin layer chromatography profiles of glycolipids (Mordarska and Pasciak, 1994).

MORPHOLOGY AND CULTURAL CHARACTERISTICS

The organism is Gram-positive, nonmotile and non-acid-fast, but otherwise its appearance in stained smears is very variable. Usually some combination of short diphtheroidal elements and longer branched filaments is seen, depending on

the medium and the age of the culture. Another characteristic feature is the presence of swollen coccoid forms. Filamentous forms are commoner in young cultures (24–48 h) and in clinical material (e.g., lacrimal sac infections).

Propionibacterium propionicum will generally grow well in standard complex media such as brain heart infusion or thioglycolate broth, especially if supplemented with 0.2% sterile rabbit serum. Schaal and Pulverer (1981) especially recommend the CC medium originally devised by Howell and Pine (1956). Good growth is obtained on the surface of the same media solidified with agar and supplemented with 4–5% rabbit or horse blood.

In liquid media the growth is generally floccular or granular: colonies on solid media may vary from smooth, regular, convex types to rough “breadcrumb” or “molar tooth” types reminiscent of *Actinomyces israelii*.

OXYGEN REQUIREMENTS AND BIOCHEMICAL REACTIONS

Propionibacterium propionicum will grow both aerobically and anaerobically, but good growth is obtained earlier and with smaller inocula under anaerobic conditions. All strains are uniformly catalase, indole, and Voges-Proskauer negative; they all reduce nitrate and hydrolyze starch (Slack and Gerencser, 1975). A variety of sugars is fermented, and most strains were positive for adonitol, sorbitol, mannitol, fructose, sucrose, lactose, trehalose, glucose, galactose, mannose and raffinose (Slack and Gerencser, 1975; Schofield and Schaal, 1981).

ANTIBIOTIC SENSITIVITY

Propionibacterium propionicum is normally sensitive to β -lactam antibiotics, tetracyclines, chloramphenicols, macrolides such as erythromycin, and a number of other antibiotics such as vancomycin. The organism is reported to be highly resistant to aminoglycosides such as gentamycin, to nitroimidazole compounds (such as metronidazole), and to peptide antibiotics (such as colistin; e.g., Schaal and Pape, 1980; Niederau et al., 1982).

SUBTYPES OF *PROPIONIBACTERIUM PROPIONICUM*

Two serovars have been described using fluorescent antibody techniques and gel diffusion tests (Gerencser and Slack, 1967; Holmberg and Forsum, 1973; Slack and Gerencser, 1975; Schaal, 1986). The two serovars are represented by the type strain for *Propionibacterium propionicum* ATCC 14157 (serovar 1), and by ATCC 29326 (serovar 2: WVU 346, F. Lentze strain “Fleischmann”). Johnson and Cummins (1972) found no crossreaction between these strains by cell wall agglutination tests, and the serovar 2 strain

(ATCC 29326, VPI 5067) showed very low DNA homology (1%) to ATCC 14157. The two serovars were found to form distinct subclusters in numerical phenetic analyses (Schofield and Schaal, 1981). Therefore, the two serovars are in fact likely to be distinguished at the species level.

ISOLATION OF *PROPIONIBACTERIUM PROPIONICUM* IN CASES OF ACTINOMYCOSIS Despite its characteristics of cell wall structure, fermentation end products, and other properties, which have led to the conclusion that taxonomically this organism should be placed in *Propionibacterium*, it is important to remember that clinically the type of disease caused cannot be distinguished from that due to *Actinomyces israelii*. The reader is therefore referred to the chapter on The Family Actinomycetaceae: The Genera *Actinomyces*, *Actinobaculum*, *Arcanobacterium*, *Varibaculum* and *Mobiluncus* in this Volume for a discussion of procedures for isolation from clinical material, the details of which are essentially the same for both organisms.

The Family Succinivibrionaceae

ERKO STACKEBRANDT AND ROBERT B. HESPELL

The rumen is a strictly anaerobic ecosystem inhabited mainly by bacteria and ciliated protozoa, plus smaller numbers of fungi. Although several hundred or more species of bacteria can be found in this ecosystem, only about thirty species are usually found at high enough levels to be considered of ecological significance. In the article written for the second edition of *The Prokaryotes* (Hespell, 1992), the species *Succinivibrio dextrinosolvens* (Bryant and Small, 1956) and *Succinimonas amylolytica* (Bryant et al., 1958) were covered in the same chapter because these species are major rumen species that have not been extensively studied. In addition, the species *Anaerobiospirillum succiniproducens* (Davis et al., 1976) was tentatively included in the chapter by Hespell (1992) since the phylogenetic relationships of *Succinivibrio dextrinosolvens*, *Succinimonas amylolytica* and *Anaerobiospirillum succiniproducens* and to other higher taxa were not known. *Succinivibrio dextrinosolvens* and *Succinimonas amylolytica* are usually found in animals with some grain in their diets. These two organisms are mainly isolated from ruminants but have also been isolated from humans suffering from bacteremia and other conditions. *Anaerobiospirillum succiniproducens* has been isolated from colonic contents of dogs but not from the rumen. *Anaerobiospirillum thomasi* (Malnick, 1997) was isolated from the throat and the colon of dogs and from human diarrheal feces. Phylogenetic analyses also linked *Ruminobacter amylophilus* (Hamlin and Hungate, 1956; Stackebrandt and Hippe, 1987) to this group. *Ruminobacter amylophilus* occurs sporadically in the rumen contents of cattle. When present, *Ruminobacter amylophilus* may be the predominant starch digester and may constitute as much as 10% of the bacterial population of the rumen.

The family Succinivibrionaceae (Hippe et al., 1999) are Gram-negative short or oval to long, or curved to helical, rods. Cells are motile (*Succinivibrio*, *Anaerobiospirillum* and *Succinimonas*) or nonmotile (*Ruminobacter*), do not form endospores, and are chemo-organotrophic and strictly anaerobic. Glucose and other carbo-

hydrates are fermented with the production of succinate and acetate; low amounts of formate and lactate may be produced. CO₂ is absorbed, and gas is not produced. Cells are catalase-negative. Nitrate is not reduced. Quinones are not detected (*Anaerobiospirillum* not tested), and cytochromes are not found in *Ruminobacter amylophilus*, the only species tested (G. Gottschalk, personal communication). Major fatty acids are saturated (35–66%) and unsaturated (19–59%), straight-chained, even-numbered fatty acids, and 16:0 and 18:0 3-OH fatty acids (4–11%). *Iso*- and *anteiso*-branched fatty acids, cyclopropane fatty acids, and odd-numbered fatty acids are absent (Moore et al., 1994). Strains are isolated from the rumen of sheep and cattle and from feces of humans, cats and dogs and from the colon of dogs (*Anaerobiospirillum*). The DNA G+C content is 39–44 mol% (data available for *Anaerobiospirillum* and *Ruminobacter*). Phylogenetically, they are members of the Gammaproteobacteria. The type genus is *Succinivibrio* (Bryant and Small, 1956).

Habitats

Succinivibrio dextrinosolvens and *Succinimonas amylolytica* are inhabitants of the rumen of cattle and sheep. The numbers of these bacteria vary depending on the diet. *Succinivibrio amylolytica* is found in the rumen of animals fed mixed diets of forages and at least some grain (Bryant et al., 1958), whereas *S. dextrinosolvens* occurs in high numbers in animals fed high-starch or other diets containing large amounts of rapidly fermentable carbohydrates (Bryant and Small, 1956; Wozny et al., 1977). Both species are involved in the digestion of starch and its breakdown products in the rumen. The occurrence of both species in ecosystems other than the rumen has not been well documented. However, the presence of *Succinivibrio* species in the blood of humans suffering from bacteremia has been reported (Southern, 1975; Porschen and Chan, 1977). In both cases, the patients had gastrointestinal tract

disorders and thus loss of gastrointestinal tract integrity might have permitted the organisms to enter the blood. If so, this suggests that *Succinivibrio* species might normally be present in low numbers in the colon of humans. *Anaerobiospirillum succiniproducens* was described on the basis of a study of three strains isolated from the throat and cecum from different beagle dogs. Spiral-shaped bacteria were also detected (but not identified) in seven of nine dogs by phase contrast microscopy of fecal homogenates or of cecal and colonic tissue sections and in four of nine dogs by scanning electron microscopy (SEM) of cecal and colon tissues. Two of the nine dogs consistently showed no spiral-shaped organisms in throat swabs. The second species, *A. thomasi*, contains animal and human strains, the latter of which were isolated during routine diagnostic examination of blood and fecal samples. The clinical strains and the methods used to isolate animal and human strains have been described previously (Malnick et al., 1990).

Ruminobacter amylophilus is one of the predominant anaerobic bacteria obtained in pure culture from the rumen contents of a Holstein cow. The bacterium thrives on basal medium supplemented with maltose and ammonia. A casein hydrolysate plus volatile fatty acids is only slightly stimulatory, and glucose and cellobiose cannot substitute for maltose (Bryant and Robinson, 1961). *Ruminobacter amylophilus* occurs sporadically in the rumen contents of cattle and, when present, may be the predominant starch digester and constitute as much as 10% of the bacterial population of the rumen. *Ruminobacter amylophilus* also occurs also in the ovine rumen (Blackburn and Hobson, 1962; Bryant and Robinson, 1961).

Isolation

Enrichment and Isolation

Currently, no procedures have been published regarding selective enrichment or isolation of either member of the family. All strains of *Ruminobacter amylophilus*, *Succinivibrio dextrinosolvens* or *Succinimonas amylolytica* have been isolated on nonspecific, habitat-simulating media used to enumerate total culturable bacteria from ruminal contents. As with other ruminal bacteria, both species are strict anaerobes. However, three strains of *S. dextrinosolvens* isolated under diverse conditions have been shown to grow on a defined medium (Gomez-Alarcon et al., 1982). This medium lacks the volatile fatty acids, peptides, and a number of other components often used in media to cultivate many species of ruminal bacteria. Thus, this medium

might be used to selectively enrich or isolate *S. dextrinosolvens*.

Anaerobiospirillum cells were originally isolated from tissue samples from the stomachs, ilea, ceca and colons of male beagle dogs. Samples were obtained by clamping the tissue with hemostats, cutting out about 1 cm from the clamped-off portion of the intestine, and quickly placing the excised tissue in pre-reduced transport broth (Aranki et al., 1969). Used for culture and microscopy, ileal and colonic tissues were removed from a region about 20 cm proximal and distal to the cecum, and stomach tissue was removed from the cardiac region. The tissues, after they were placed in a glove box, were homogenized in a blender; the homogenates were diluted and plated on a pre-reduced medium in the glove box for 48 to 72 h prior to use. Tubed transport-broth dilution medium was prepared, sterilized in screw-capped tubes, and, to reduce its oxygen concentration, put into an anaerobic glove box (containing 80% N₂, 10% H₂, and 10% CO₂) with screw caps loose for at least 48 h prior to use (Davis et al., 1976). Using procedures to isolate human strains, *A. thomasi* strains were isolated during routine diagnostic examination of blood and fecal samples. The clinical strains and methods used to isolate animal and human strains have been described previously (Malnick et al., 1990).

Cultivation Media

Strains of *Succinivibrio* and *Succinimonas* species can be grown on a variety of complex, rumen fluid-containing media (Bryant and Burkey, 1953; Bryant and Robinson, 1961) or on more defined media in which the rumen fluid has been replaced by trypticase, yeast extract, hemin, and volatile fatty acids (Caldwell and Bryant, 1966; Hespell and Bryant, 1981). A typical complex medium for both species and a chemically defined medium for *S. dextrinosolvens* (adapted from Gomez-Alarcon et al., 1982) are shown in Table 1. Since both species produce succinate as a fermentation product, the use of a bicarbonate-carbonic acid system is needed to provide carbon dioxide and a means of buffering. Ammonium ions serve as a major nitrogen source for both species. *Succinimonas amylolytica* has a limited range of fermentable substrates (i.e., glucose, maltose, dextrin and starch). *Succinivibrio dextrinosolvens* also ferments these substrates plus galactose and xylose, but starch is only partially used and is incompletely hydrolyzed. Neither species ferments amino acids or peptides.

Anaerobiospirillum succiniproducens is routinely grown on Wikins-Chalgren Anaerobe Broth (Oxoid CM 643), supplemented with 1 g/l of NaHCO₃, 1 mg/l resazurin and 0.3 g/l L-

Table 1. Media for *S. amylolytica* and *S. dextrinosolvens*.^a

Ingredient	Amount per 100ml of medium	
	Medium 1	Medium 2
Carbohydrate (5%) ^b	5.0 ml	5.0 ml
Trypticase	0.5 g	—
Serine	—	30 mg
Leucine	—	40 mg
Methionine	30 mg	30 mg
Yeast extract	0.2 g	—
<i>p</i> -Aminobenzoic acid	—	10 µg
Ammonium chloride (5.3%)	1.0 ml	1.0 ml
Resazurin (0.1%)	0.1 ml	0.1 ml
IVI VFA solution ^c	3.0 ml	—
L-Cysteine-HCl (2.5%) ^b	1.0 ml	1.0 ml
Mineral A ^d	4.0 ml	4.0 ml
Mineral B ^e	4.0 ml	4.0 ml
Ferrous sulfate	0.3 mg	0.3 mg
Trace minerals ^f	0.5 ml	0.5 ml
Hemin plus 1,4-napthoquinone ^g	1.0 ml	1.0 ml
Sodium carbonate (8%) ^h	5.0 ml	5.0 ml
Distilled water	76.0 ml	79.0 ml

Medium 1 is for both species and medium 2 for *S. dextrinosolvens*.

^aBoth media are prepared under carbon dioxide; final pH 6.8. The defined medium is for *S. dextrinosolvens* only.

^bAutoclaved separately; prepared and stored under a nitrogen gasphase.

^cPrepared by adding 7ml acetic acid, 3ml propionate, 2ml butyrate, and 0.6ml each of isobutyrate, 2-methylbutyrate, and isovalerate to 700ml of 0.2M NaOH. Adjust to pH 7.0 with NaOH and to a final volume of 1 liter.

^dMineral A = 0.5% K₂HPO₄.

^eMineral B = 1.0% KH₂PO₄, 1.2 NaCl, 0.58% NaSO₄, 0.16% CaCl₂ × 2H₂O, and 0.25% MgSO₄ × 7H₂O.

^ftrace minerals contained 10mg each of ZnSO₄ × 7H₂O, H₃BO₃, NaSeO₃, Na₂MoO₄ × 2 H₂O, NiCl₂ × 6 H₂O; 5mg CuSO₄ × 5 H₂O, and 2mg of Al(SO₄)₂ × 12 H₂O made to 100ml with distilled water.

^gsolution made by dissolving 25mg of 1,4-napthoquinone in 2ml of 95% ethanol and combining with 10mg of hemin dissolved in 50ml of 0.01M NaOH and 38ml distilled water.

^hautoclaved separately; prepared, equilibrated, and stored under a carbon dioxide gas phase.

cysteine. *A. succiniproducens* has also been cultivated on fastidious anaerobe agar (Lab M, Topley House, Bury, England) (Malnick, et al., 1990) and in the Bactec 9240 anaerobic system (Wecke and Horbach, 1999).

A selective medium has been described by Malnick et al. (1990) for *Anaerobiospirillum* spp, using Skirrow campylobacter medium (Skirrow, 1977) supplemented with polymyxin (2,500 IU/liter), vancomycin (20 mg/liter), sulfamethoxazole (100 mg/liter), Victoria blue B, (250 mg/liter, dissolved in 4 ml of ethanol) and horse blood (lysed with saponin, 40 ml/liter). After 48 h colonies of *Anaerobiospirillum* spp were 1–2 mm in diameter, uniform dark blue and low convex.

A. thomasi strains grow on fastidious anaerobe agar (Lab M, Topley House, Bury, England) with added horse blood (50 ml/liter) incubated at 37°C in an anaerobic hood. Alternatively, Wilkins Chalgren Anaerobe Broth (Oxoid CM

643), prepared anaerobically under 80% N₂ + 20%, can be used.

Preservation of Cultures

All species can be maintained for long times by storage of cultures in liquid nitrogen or ultracold freezers (Hespell and Canale-Parola, 1970). All species can be maintained as freeze-dried cultures. Short-term storage is possible by placing glycerol cultures in normal (–20°C) freezers (Teather, 1982). *Ruminobacter amylophilus* is routinely maintained in the DSMZ-German Collection of Microorganisms and Cell Cultures in medium consisting per 1000 of distilled water 0.45 g (each) KH₂PO₄ and K₂HPO₄, 0.9g (NH₄)₂SO₄, 0.9g NaCl, 0.18g MgSO₄ × 7H₂O, 5.0g soluble starch, 10.0g casitone (Difco), 1.0 mg resazurin, 0.5 g cysteine hydrochloride, and 6.0 g

NaHCO₃, pH 7.0, at a gas atmosphere of 100 CO₂.

Phylogeny

On the basis of 16S rRNA gene sequence similarities, members of the family Succinivibrionaceae are members of the Gammaproteobacteria (Hippe et al., 1999). The phylogenetic distance between type species of the family is only remote (97.7–92.7% similarity) and even the type strains of the two *Anaerobiospirillum* species, *A. succiniproducens* and *A. thomasii*, share only 92.8% similarity. The family is a phylogenetic neighbor of the family Aeromonadaceae and of a cluster consisting of the genera *Oceanisphaera*, *Oceanimonas* and *Ferrimonas*. Sequence similarities between members of Succinivibrionaceae and type species of neighboring genera range between 84.6 and 88.5%. All species described so far can unambiguously be identified by their 16S rRNA gene sequence (Tee et al., 1998; Misawa et al., 2002). As the type strains share about 93% sequence similarity, differences of seven percent sequence dissimilarity account for about 100 nucleotides which are mainly located in the variable regions of the sequence (i.e., positions 68–87, 126–218, 446–473, and 991–1037). This distribution allows identification of at least those strains that are highly related to the type strains on the basis of a continuous stretch located between positions 50 and 500. This stretch can be amplified and sequenced using primers located at positions 18 forward and 530 reverse (Lane, 1991).

16S rRNA gene sequence-specific polymerase chain reaction (PCR) primers were used to detect Proteobacteria in rumen fluid taken from a ruminally fistulated Holstein cow. Though originally designed to detect type-1 methanotrophs (Wise et al., 1999) placed in the Gammaproteobacteria, the study identified five sequences moderately related to *Succinivibrio dextrinosolvens* (Mitsumori et al., 2002). Species-specific 16S rRNA gene primers were designed and used in a real-time PCR experiment to determine the population shift when the diet of cows was changed from hay to grain. Though the *Ruminococcus amylophilus* and *Succinivibrio dextrinosolvens* population was still high at day three after the shift, cell numbers of both species declined significantly after 28 days and were hardly detectable (Tajima et al., 2001). The primers for *Ruminococcus amylophilus* ATCC 29744 were CAACCAGTCGCATTCAGA (forward) and CACTACTCATGGCAACAT (reverse) and for *Succinivibrio dextrinosolvens* ATCC 19716^T TGGGAAGCTACCTGATA GAG

(forward) and CCTTCAGAGAGGTTCTCACT (reverse).

A phylogenetic dendrogram of the ATP/ADP-dependent phosphoenolpyruvate carboxykinase amino acid sequence of *Anaerobiospirillum succiniproducens* indicated that this species clusters with those of other members of Gammaproteobacteria, confirming the 16S rRNA gene sequence-based phylogenetic position (Laivenieks et al., 1997).

Taxonomy

Succinivibrio

Succinivibrio dextrinosolvens forms light tan, entire, translucent surface colonies that are generally only 1–2 mm in diameter. Occasionally, colonies may be irregular, raised, and yellowish. Subsurface colonies are lenticular and equally small. However, in media having low agar concentrations (0.2–0.6%), subsurface colonies take on a diffuse, white, furry appearance. The cells appear singly or in pairs of small, curved rods (usually 0.3–0.5 × 2.0–4.0 μm) with pointed ends. With newly isolated strains, helical or twisted filaments of 2–4 coils composed of two or more cells are common. These filaments often show rotational motility. This helical characteristic varies with strains and can be lost during successive subcultures in the laboratory, resulting in single or pairs of slightly curved rods. Under adverse cultural conditions many strains can form pleomorphic shapes—usually large, swollen rods or spherical bodies. Cells invariably stain Gram negatively and are motile. The motility is translational with a vibrating movement. The flagellation arrangement is polar and monotrichous.

A large production of acetic and succinic acids with an uptake of carbon dioxide is the most common fermentation pattern for *Succinivibrio* strains fermenting glucose (Bryant and Small, 1956; Scardovi, 1963). Small, variable amounts of formate and lactate can be made. Hydrogen gas, propionate, and butyrate are not made. Good growth occurs at incubation temperatures of 30–40°C, but no growth occurs at 22°C or 45°C. Biochemical tests for nitrate reduction, catalase, and production of indole, acetoin, or hydrogen sulfide are all negative. Presently, all ruminal strains are considered to constitute a single species, *Succinivibrio dextrinosolvens* (Bryant, 1984b). The succinivibrio-like strains isolated from blood samples (Southern, 1975; Porschen and Chan, 1977) appeared to have lophotrichous flagellation and are probably not true isolates of this species, but further studies are needed to verify this.

Succinimonas

Succinimonas strains form surface colonies that are light tan in color, translucent, smooth and convex. Even after prolonged incubation, the colonies are only 0.6–1.5 mm in diameter. Colonies within agar media are lenticular in shape. Typically, the cell morphology is that of a short, oval rod or coccobacillus (1–1.5 $\mu\text{m} \times 1.2$ –3.0 μm). The cells appear singly or in pairs but can form clumps in older cultures. The cells always stain Gram negatively. In wet-mount preparations, most cells show some degree of translational motility, which ceases when oxygen is present. Often cells which have become attached to the glass surface display a rotational movement about one cell end. The flagellar arrangement is polar and monotrichous. Some cells may show granules near the cell periphery. The nature of these granules is unknown, but they may be composed of glycogen, which is found in a number of species of ruminal bacteria. In liquid media, growth is even and cells are dispersed, but generally dense turbidities do not occur.

The major products formed from glucose are acetic and succinic acids, and the formation of these products requires a large uptake of carbon dioxide. No hydrogen gas, formate, lactate or ethanol is produced, but trace amounts of acetoin and/or propionate may be formed. No strains are known to hydrolyze gelatin and production of hydrogen sulfide, indole or catalase has not been observed. Growth occurs at 30–39°C but not at 22°C or 45°C. Strain differences are rather minimal and all strains are considered to be isolates of a single species, *Succinimonas amyolytica* (Bryant, 1984a).

Anaerobiospirillum

The genus is defined by Gram-negative helical rods with rounded ends (usually 0.6–0.8 $\mu\text{m} \times 3$ –15 μm), although some cells are up to 32 μm long. Cells are motile by means of bipolar tufts of flagella. Cells usually occur singly. Endospores are not formed. Cells are strictly anaerobic, catalase and oxidase negative, do not hydrolyze esculin, hippurate or urea, and do not reduce nitrate. Carbohydrate metabolism is fermentative. The major products from glucose metabolism are succinic and acetic acids; traces of lactic and formic acids may also be formed. The growth temperature is 33–43°C with an optimum of 37°C.

Anaerobiospirillum succiniproducens is a Gram-negative helical rod (0.6–8.0 $\mu\text{m} \times 3.0 \mu\text{m}$) with rounded ends; some cells reach 20 μm in length. The helix diameter is 0.9–1.1 μm and the wavelength is about 1.3–1.7 μm . *Anaerobiospirillum thomasi* cells are helical rods (0.5–0.7 \times 5–32 μm). Flat colonies with even, sometimes

spreading edges are 1–2 mm in diameter after 24–48 h on horse blood agar. Hemolysis does not occur. The enzymes detected with an API ZYM kit are leucine arylamidase and *N*-acetyl- β -glucosaminidase. Enzymes not detected with an API ZYM kit include acid and alkaline phosphatases, esterase (C-4), esterase-lipase (C-8), lipase (C-14), valine arylamidase, cystine arylamidase, trypsin, chymotrypsin, phosphohydrolase, DL- and D-galactosidase, β -D-galactosidase, β -glucuronidase, β -glucosidase, mannosidase, and L-fucosidase.

Ruminococcus

Without phylogenetic information this species could be misclassified as *Prevotella ruminicola* (Shah and Collins, 1990) or *Fibrobacter succinogenes* (Montgomery et al., 1988), organisms previously classified as members of *Bacteroides*. *Ruminobacter amylophilus* differs considerably from these organisms, as well as *Fusobacterium*, *Leptotrichia* and members of genera previously grouped in the family Bacteroidaceae as defined by Holdeman et al. (1984) using a combination of properties, including morphology, the pattern and end products of carbohydrates utilized, fermentation products, mol% G+C of their DNA, and fatty acid composition. On the basis of metabolic properties, *Ruminobacter* can also be distinguished from species of several other genera defined by Gram-negative staining, but phylogenetically Gram-positive obligate-anaerobes, viz., *Acidaminobacter* (Stams and Hansen, 1984), *Ilyobacter* (Stieb and Schink, 1985), *Pelobacter* (Schink and Pfennig, 1982a), *Propiogenium* (Schink and Pfennig, 1982b) and *Propionispira* (Schink et al., 1982).

Following the loss of the first culture of *Bacteroides amylophilus* (Hamlin and Hungate, 1956), organisms conforming to the original description of *B. amylophilus* have been isolated frequently from the rumen (Blackburn and Hobson, 1962; Bryant and Robinson, 1961; Caldwell et al., 1969; Holdeman et al., 1977). A neotype strain of *B. amylophilus* was proposed (Cato et al., 1978) for strain H 18 isolated by Blackburn and Hobson (1962). As this species differed from authentic *Bacteroides* species in fatty acid composition (Miyagawa et al., 1979) and the lack of sphingophospholipids (Kunsman and Caldwell, 1974; Miyagawa et al., 1978; Miyagawa et al., 1979; and Shah and Collins, 1983), the removal of *B. amylophilus* from *Bacteroides sensu stricto* has been suggested. These conclusions were supported by the finding that *B. amylophilus* and authentic members of *Bacteroides* belong to different main phylogenetic lines of descent (Woese et al., 1985; Martens et al., 1987). *Bacteroides amylophilus* grouped certain members of the so

called “ γ -subclass of the class Proteobacteria” (today named “Gammaproteobacteria”), e.g., enterobacteria, vibrios, oceanospirilla, alteromonads, while authentic *Bacteroides* formed a coherent cluster within the *Bacteroides*–*Cytophaga*–*Flavobacterium* line of descent (Paster et al., 1985). Consequently, *Bacteroides amylophilus* was reclassified as *Ruminobacter amylophilus* (Stackebrandt and Hippe, 1986). The generic name “*Ruminobacter*,” originally used to describe Gram-negative, nonmotile, anaerobic chemoheterotrophic cellulose-fermenting bacteria (Kaars Sijpesteijn, 1949), was considered genus incertae sedis (Prévot, 1966). But at the same time, *Bacteroides* species “*B. amylogenes*,” *B. ruminicola*, *B. succinogenes* and the noncellulolytic species *B. amylophilus* were transferred into this genus. As the taxon *Ruminobacter* was not included in the Approved Lists of Bacterial Names (Skerman et al., 1980), it had no standing in nomenclature and could be used to accommodate the former *B. amylophilus*.

Ruminobacter amylophilus forms small, tan colonies on the surface of agar media. However, the cell morphology is distinctly different from that of the other members of the family (Table 2). The cells are larger ($0.9\text{--}1.2 \times 1\text{--}3 \mu\text{m}$ long), tend to form pleomorphic, swollen shapes, and most importantly, are nonmotile (Hamlin and Hungate, 1956). In addition, *R. amylophilus* does not grow on glucose. *Ruminobacter amylophilus* produces acetate, formate and succinate as major fermentation products, and trace amounts of lactate and ethanol may also be formed.

Cells are Gram-negative, oval to long rods with tapered or round ends, and some cells are swollen forms and irregularly curved ($0.9\text{--}1.2 \mu\text{m} \times 1.1\text{--}8.0 \mu\text{m}$; Cato et al., 1978). Surface colonies on rumen fluid-glucose-cellobiose agar roll tubes are 1 mm in diameter, circular, entire, slightly convex, translucent, smooth, glistening, and white to tan. Colonies in laked-blood roll streak tubes are pinpoint to 2 mm in diameter, circular, entire to slightly erose, convex to slightly erose, convex to umbonate, translucent, colorless, shiny and smooth after incubation for 4 days. Growth is sparse on freshly prepared blood agar plates incubated anaerobically. Surface colonies on rumen fluid-glucose-cellobiose agar roll tubes are 1 mm in diameter, circular, entire, slightly convex, translucent, smooth, glistening, and white to tan. Colonies in deep agar are $0.8\text{--}1$ mm in diameter, lenticular, entire or irregular, white, soft and butyrous. Growth is not stimulated by amino acids, volatile fatty acids (Miura et al., 1980), vitamins or hemin (Macy and Probst, 1979). No colonies appear on egg yolk agar plates and on the surface of plates incubated in an aerobic jar. Rumen fluid is not required

(Bryant and Robinson, 1961) for growth, but ammonia is essential as nitrogen. Carbon dioxide is fixed and ammonia is assimilated.

Biochemical and Physiological Properties

The carbohydrate fermentation pathways in *Succinivibrio dextrinosolvens* have been studied by Scardovi (1963) and O'Herrin and Kenealy (1993). Enzymatic activities of the Embden-Meyerhof pathway were present in cell-free extracts, but enzymes of the hexose monophosphate pathway were absent. Phosphoenolpyruvate was found to undergo carboxylation to form oxaloacetate as the product, with ADP acting as the phosphate acceptor. Presumably, the oxaloacetate mainly undergoes reduction to form succinate and is partially used in biosynthetic transamination reactions to form amino acids. The pathways for assimilation of ammonia by *S. dextrinosolvens* have been elucidated with strain C18 (Patterson and Hespell, 1985). This strain was shown to possess glutamine synthetase, urease, glutamate dehydrogenase, glutamate-oxaloacetate transaminase and aspartate synthase. When grown in continuous culture under ammonia limitation, cells contained high levels of glutamine synthetase and urease, but glutamate dehydrogenase activity was low. The opposite pattern is observed with growth in the presence of ample ammonia. The glutamate dehydrogenase was reduced nicotinamide adenine dinucleotide phosphate (NADPH)-linked. The glutamine synthetase was regulated by an adenylation-deadenylation mechanism, allowing for rapid enzyme inactivation when high levels of ammonia are present.

Zeikus and coworkers have performed detailed analysis of the phosphoenolpyruvate carboxykinase (PEP) catalyzing the reversible formation of oxalacetate and ATP from PEP, ADP and CO_2 in *Anaerobiospirillum succiniproducens*, e.g., purification and characterization (Podkovyrov et al., 1993; Jabalquinto et al., 1999), site-directed mutagenesis (Jabalquinto et al., 2002a; Jabalquinto et al., 2002b; Jabalquinto et al., 2003; Jabalquinto et al., 2004), as well as its cloning, sequencing and overexpression in *E. coli* (Laivenieks et al., 1997).

In the presence of CO_2 , *Ruminococcus amylophilus* ferments maltose to succinate: $2 \text{ maltose} + 2 \text{ CO}_2 \rightarrow 2 \text{ succinate} + 2 \text{ acetate} + 2 \text{ formate}$ (Kühn, 1979). This method of succinic acid production has been patented (United States patent number 5,143,833). The organism is able to grow well in basal medium supplemented with starch. Starch broth cultures are turbid and have a final

Table 2. Morphological and metabolic properties differentiating members of the family Succinivibrionaceae.

Properties	Anaerobiospirillum				<i>Ruminococcus</i>
	<i>Succinivibrio</i>	<i>Succinimonas amylolytica</i>	<i>succiniproducens</i>	<i>thomasi</i>	
Morphology	Curved rods	Spherical	Helical rods, sometimes spheres	Helical rods	Oval to long rods with tapered or round ends
Motility	+	+	+	+	–
Flagella	Monotrichous, polar flagella	Monotrichous, polar flagella	Bipolar, tuft of 12–16 flagella ^a	Bipolar tufts	–
Major fermentation end products	Succinate, acetate	Succinate, acetate	Succinate, acetate	Succinate, and acetate	Succinate, acetate, and formate
Fermentation of carbohydrates	ND	ND	Fructose, glucose lactose, maltose, sucrose, raffinose, inulin, β-D-galactoside, and α-D-glucoside	Adonitol, galactose, glucose, and maltose	Dextrin, glycogen, maltose and starch
Not fermenting	ND	ND	Adonitol, L-arabinose, cellobiose, dulcitol, esculin, galactose, mannitol, rhamnose, salicin, sorbitol, and D-xylose	Fructose, cellobiose, inulin, lactose, mannitol, raffinose, salicin, sorbitol, sucrose, and trehalose	Amygdalin, arabinose, cellobiose, esculin, fructose, D-galactose, D-glucose, glycerol, <i>i</i> -inositol, inulin, lactose, D-mannitol, raffinose, L-rhamnose, ribose, salicin, sucrose, trehalose, D-xylose
Negative for	Catalase nitrate reduction, and production of indole, acetoin, or hydrogen sulfide	ND	Catalase, oxidase nitrate reduction fermentation of gelatin liquefaction, indole production, lipase, meat digestion, hydrolyze esculin, hippurate, or urea	Catalase, nitrate reduction oxidase activity, and hydrolysis of esculin, hippurate, and urea	Cellulose milk and meat digestion
Mol% G+C	ND	ND	44	39–42	40–42
Habitat, isolated from	Rumen of cattle and sheep, septicemia	Rumen of cattle and sheep	Colon and throat of dogs	Feces of cats and dogs and from human diarrheal feces	Rumen of cattle and sheep
Type strain	None	None	NCTC 11536 ^T	NCTC 12467 ^T	ATCC 29744 ^T

^aDetailed ultrastructure analyses are provided by Wecke and Horbach (1999). Symbols and abbreviations: +, present; –, absent; and ND, no data. From Bryant and Small (1956), Bryant et al. (1958), Davis et al. (1976), Malnick (1979), and Stackebrandt and Hippe (1986).

pH of 5.3–5.5. Amylase production is stimulated by Tween 80 (McWethy and Hartman, 1977).

Clinical Significance

Reports on *Succinivibrio dextrinosolvens* bacteremia (Southern, 1975; Porschen and Chan, 1977) and *Succinimonas* spp. bacteremia (Johnson and Finegold, 1987) are rare. On the other hand, there are several reports of *Anaerobiospirillum* infection in humans. The infections have been diagnosed via evidence of bacteremia or septicemia, but the full extent of the organisms's pathogenicity remains to be determined. The study by McNeil et al. (1987) indicated that most of the patients from which members of the genus had been isolated had an underlying disorder like arteriosclerosis, malignancy, liver cirrhosis, diabetes mellitus, and dental infections, and most suffered from gastrointestinal symptoms (Malnick et al., 1983; Park et al., 1986; Marcus et al., 1996; Goddard et al., 1998; Pienaar et al., 2003). Some of the patients owned pet dogs and cats (Goddard et al., 1998). Two *Anaerobiospirillum* strains (identified by 16S rRNA gene sequencing) with different morphologies were isolated from a puppy with bloody diarrhea (Misawa et al., 2002). Recently, strains of *A. succiniproducens* were isolated from blood of AIDS patients in Australia (Tee et al., 1998) and Europe (Wecke and Horbach, 1999). Strains of this species have also been isolated from the blood of a young child with bacteremia and no underlying disease; this led the authors Rudensky et al. (2002) to alert microbiologists and physicians to these organisms, which are resistant to antibiotics prescribed for infections caused by the morphologically similar *Campylobacter* spp.

Application

Anaerobiospirillum succiniproducens has been used in anaerobic fermentation processes for the production of succinate-based animal feed additive using whey as a carbohydrate source. Between 60 and 90% succinate yield was achieved depending on the production process (60% for continuous culture, 80% in batch cultivation, and 90% in a variable volume fed process). The end products were determined by the amount of CO₂ added to the process. Under conditions of excess CO₂, more than 90% of the whey lactose was consumed and the product ratio of succinate to acetate was 4:1. Lactate was the main end product when no excess CO₂ was provided (Samuelov et al., 1999). Even higher yields of succinate were obtained (93–

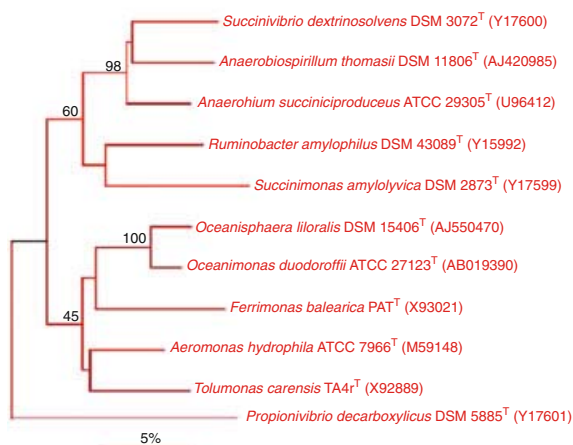

Fig. 1. Dendrogram showing the phylogenetic position of representatives of the family Succinivibrionaceae (Hippe et al., 1999) next to its phylogenetic neighbors within the Gammaproteobacteria. The tree was constructed by the neighbor-joining method (Saitou and Nei, 1987), using corrected distance values (Jukes and Cantor, 1969). Sequences of members of the Enterobacteriaceae were used to root the dendrogram. Bootstrap values (expressed as percentages of 500 replications) of 40% or more, are indicated at the branch points (Felsenstein, 1993). Bar = 5% sequence divergence.

95%) when yeast extract, polypeptones and glucose were added to whey and the ratio of succinic acid to acetic acid was increased to 5.1:1 (Lee et al., 2000). With glycerol as a carbon source, the yield of succinic acid reached 133% when the ratio of succinic acid to acetic acid was increased to 25.8:1. In the presence of yeast extract, the yield even increased to 160% (succinic acid:acetic acid = 31.7:1; Lee et al., 2001). When grown on minimal salts medium, wood hydrolysates (equivalent to 27 g of glucose per liter), and corn steep liquor (10 g), the succinate yield was 24 g per liter (88% [w/w] glucose; Lee et al., 2003).

The Family Actinomycetaceae: The Genera *Actinomyces*, *Actinobaculum*, *Arcanobacterium*, *Varibaculum*, and *Mobiluncus*

KLAUS P. SCHAAL, ATTEYET F. YASSIN AND ERKO STACKEBRANDT

Introduction

The family Actinomycetaceae was created by Buchanan in 1918 and was originally used to accommodate many diverse organisms such as members of the genera *Actinobacillus*, *Lep-totrichia*, *Actinomyces* and *Nocardia*. After several revisions, membership of the family was restricted to bacterial species that appeared to be linked taxonomically by the following phenotypic characteristics: ability to produce Gram-positive, branching and, later on, fragmenting filaments without aerial hyphae and spores; comparatively exacting nutritional requirements; facultatively anaerobic (capnophilic) to anaerobic growth; and fermentative carbohydrate metabolism (Slack, 1974; Slack and Gerencser, 1975).

Taking into account these common characters, the family Actinomycetaceae was thought to include the genera *Actinomyces*, *Arachnia*, *Bifidobacterium*, *Bacterionema* and *Rothia* (Slack, 1974). However, the validity of this family concept was increasingly questioned after modern and more relevant taxonomic techniques such as chemotaxonomic, numerical phenetic, and molecular genetic procedures had been applied to the respective organisms.

As currently defined, the family Actinomycetaceae (Buchanan 1918) with the type genus *Actinomyces* (Harz 1877) is a member of the suborder Actinomycineae (Stackebrandt et al., 1997), order Actinomycetales (Buchanan 1918; Skerman et al., 1980), emend. Stackebrandt et al., 1997. This order has been included in the class Actinobacteria by Stackebrandt et al. (1997). The type species is *Actinomyces bovis* (Harz, 1877). Besides the genus *Actinomyces*, the family includes the genera *Arcanobacterium* (Collins et al., 1982c) with the type species *Arcanobacterium haemolyticum*, *Mobiluncus* (Spiegel and Roberts, 1984a), type species *Mobiluncus curtisii*, *Actinobaculum* (Lawson et al., 1997), type species *Actinobaculum suis*, and *Varibaculum* (Hall et al., 2003e), type species *Varibaculum cambriense*.

The species that are currently considered valid members of the family and the sources of their isolation have been compiled in Table 1. *Actinomyces* species that were reclassified are listed in Table 2, and synonyms and basonyms of members of the Actinomycetaceae have been compiled in Table 3. Many new species were described after the chapter on the genera *Actinomyces*. *Arcanobacterium* and *Rothia* had been published in the second edition of *The Prokaryotes* (Schaal, 1992b), and the phylogeny of the order Actinomycetales has been studied extensively. In contrast, little progress has been made with respect to physiology and chemotaxonomy, and the ecological significance of many of the novel species is not fully understood. This is also exemplified by the almost complete lack of information on as yet uncultured actinomycetes in public databases, which indicates that the natural environment of these organisms has hardly been covered by molecular surveys (exceptions are Oaster et al. [2001] and K. E. Kempself et al. [unpublished observation], accession numbers AJ404525, AJ405526 and AJ405527). Furthermore, very little information is available on gene sequences other than 16S rRNA genes, coding for, e.g., fimbrial structural subunits and fimbria-associated proteins (Yeung et al., 1998), urease (Morou-Bermudez and Burne, 1999), sialidase (Henningsen et al., 1991), neuraminidase (Jost et al., 2001), phospholipase (Cuevas and Songer, 1993), and genes involved in carbohydrate metabolism (L. J. Bergeron, unpublished observation; AF228582). Thus, the emphasis of the biology of the Actinomycetaceae still focuses on their epidemiology and identification in the clinical field.

Phylogeny

Actinomyces bovis belonged to one of the first species subjected to 16S rRNA analysis (Stackebrandt and Woese, 1981). By now, almost complete 16S rRNA gene sequences are available for all of the type strains of the species

Table 1. Alphabetical list of species of the family Actinomycetaceae.

Described as	Type strains deposited in selected collections	Sources of isolation	Original description
<i>Actinomyces</i>			
<i>Actinomyces bovis</i>	ATCC 13683 = CCUG 31996 = DSM 43014	Bovine actinomycosis—lumpy jaw, cattle	Hartz, 1877
<i>Actinomyces bowdenii</i>	CCUG 37421	Abscesses, dogs, and pleural fluid, cat	Pascual et al., 1999
<i>Actinomyces canis</i>	CCUG 41706	Vagina and purulent lesions, dogs	Hoyles et al., 2000
<i>Actinomyces cardiffensis</i>	CCUG 44997	Clinical sources including pleural fluid, brain, jaw, pericolic and ear abscesses, and intrauterine contraceptive devices, humans	Hall et al., 2002
<i>Actinomyces catuli</i>	CCUG 41709	Mediastinal tissue and blood clot, dogs	Hoyles et al., 2001a
<i>Actinomyces coleocanis</i>	CCUG 41708	Vagina, dog	Hoyles et al., 2002
<i>Actinomyces denticolens</i>	ATCC 43322 = NCTC 11490 = CCUG 32758 = DSM 20671	Supragingival dental plaque, dairy cattle	Dent and Williams, 1984a
<i>Actinomyces europaeus</i>	ATCC 700353 = CCUG 32789 A	Femur tissue, various abscesses, atheroma cyst, and decubital ulcer, humans	Funke et al., 1997
<i>Actinomyces funkei</i>	CCUG 42773 = CIP 106713	Blood cultures (endocarditis) and localized lesions, humans	Lawson et al., 2001
<i>Actinomyces georgiae</i>	ATCC 49285 = CCUG 32935 = DSM 6843	Gingival crevice with and without periodontitis, humans	Johnson et al., 1990
<i>Actinomyces gerencseriae</i>	ATCC 23860 = CCUG 32936 = DSM 6844	Parotid abscess and various other manifestations of actinomycosis, humans	Johnson et al., 1990
<i>Actinomyces graevenitzii</i>	CCUG 27294 = CIP 105737	Bronchial secretions, sputum, and osteitis of the jaw, humans	Pascual Ramos et al., 1997
<i>Actinomyces hongkongensis</i>	HKU8 = DSM 15629 = LMG 21939	Pus from pelvic actinomycosis, human	Woo et al., 2003
<i>Actinomyces hordeovulneris</i>	ATCC 35275 = CCUG 32937 = DSM 20732	Pleuritis, pericarditis, peritonitis, visceral abscesses, septic arthritis and recurrent localized infections, dogs	Buchanan et al., 1984
<i>Actinomyces howellii</i>	ATCC 43323 = CCUG 32757	Dental plaque, dairy cattle	Dent and Williams, 1984b
<i>Actinomyces hyovaginalis</i>	ATCC 51367 = CCUG 35604 = DSM 10695	Purulent vaginal discharge, pigs	Collins et al., 1993
<i>Actinomyces israelii</i>	ATCC 12102 = CCUG 18307 = DSM 43320	Various actinomycotic lesions including cervicofacial abscesses, pulmonary lesions, abdominal and pelvic abscesses, brain abscesses, and lacrimal canalculitis, humans	Kruse, 1896 Lachner-Sandoval, 1898
<i>Actinomyces marinammalium</i>	CCUG 41710 = CIP 106509	Various internal organs and small intestine, dead seals and a porpoise	Hoyles et al., 2001b
<i>Actinomyces meyeri</i>	ATCC 35568 = CCUG 21024 = DSM 20733	Periodontal sulcus, brain and other abscesses, pleural fluid, human	Cato et al., 1984
<i>Actinomyces naeslundii</i>	ATCC 12104 = (NCTC 10301, CCUG 2238) = DSM 43013	Dental plaque, cervicovaginal secretions, abscesses, empyemas, eye infections, human	Thompson and Lovestedt, 1951
<i>Actinomyces nasicola</i>	R2014 = CCUG 46092 = CIP 107668	Pus from <i>antrum nasi</i> , human	Hall et al., 2003a
<i>Actinomyces neuui</i> subsp. <i>anitratus</i>	ATCC 51849 = CCUG 32253 = DSM 8577	Abscesses, blood cultures, human	Funke et al., 1994
<i>Actinomyces neuui</i> subsp. <i>neuui</i>	ATCC 51847 = CCUG 32252 = DSM 8576	Abscesses, blood cultures, infected mammary hematoma, human	Funke et al., 1994
<i>Actinomyces odontolyticus</i>	ATCC 17929 = (NCTC 9935, CCUG 20536) = DSM 43760	Dental plaque, carious lesions, abscesses, eye infections, human	Batty, 1958
<i>Actinomyces oricola</i>	R5292 = CCUG 46090 = CIP 107639	Dental abscess, human	Hall et al., 2003b
<i>Actinomyces radidentis</i>	CCUG 36733 = CIP 106352	Infected dental root canals, human	Collins et al., 2000

Table 1. Continued

Described as	Type strains deposited in selected collections	Sources of isolation	Original description
<i>Actinomyces radigueae</i>	ATCC 51856 = CCUG 32394 = DSM 9169	Mixed wound infections, human	Wüst et al., 1995, emend. Vandamme et al., 1998
<i>Actinomyces slackii</i>	ATCC 49928 = (NCTC 11923, CCUG 32792)	Supragingival plaque, dairy cattle	Dent and Williams, 1986
<i>Actinomyces suimastitidis</i>	CCUG 39276 = CIP 106779	Chronic granulomatous mastitis, pig	Hoyles et al., 2001c
<i>Actinomyces turicensis</i>	ATCC 51857 = CCUG 32401 = DSM 9168	Mixed wound infections, human	Wüst et al., 1995, emend. Vandamme et al., 1998
<i>Actinomyces urogenitalis</i>	CCUG 38702 = CIP 106421	Vaginal secretions, urine, genital infections, human	Nikolaitchouk et al., 2000
<i>Actinomyces vacuaxillae</i>	CCUG 46091 = CIP 107423	Jaw lesion, cow	Hall et al., 2003
<i>Actinomyces viscosus</i>	ATCC 15987 = CCUG 14476 = (DSM 43327 [serovar 1], ATCC 19246 [serovar 2])	Subgingival plaque and periodontal disease, hamster; cervical plaque, rat; dental plaque, human; various suppurative processes in man and animals	Howell et al., 1965 Georg et al., 1969
<i>Actinobaculum</i>			
<i>Actinobaculum massiliae</i>	CIP 107404	Urine, human	Greub and Raoult, 2002
<i>Actinobaculum schaalii</i>	CCUG 27420 = CIP 105739	Blood and urine, human	Lawson et al. 1997
<i>Actinobaculum suis</i>	ATCC 33144 = CCUG 19206 = DSM 20639	Cystitis, pyelonephritis, metritis, urine, and semen, pigs	Wegienek and Reddy, 1982a Lawson et al., 1997
<i>Actinobaculum urinale</i>	CCUG 46093 = CIP 107424	Urine, human	Hall et al., 2003
<i>Arcanobacterium</i>			
<i>Arcanobacterium bernardiae</i>	ATCC 51727 = CCUG 33419 = DSM 9152	Blood, abscesses, and various other clinical sources, human	Funke et al., 1995
<i>Arcanobacterium haemolyticum</i>	ATCC 9345 = CCUG 17215 = DSM 20595	Pharyngitis, wound infections, soft tissue infections, endocarditis, septicemia, human	Pascual Ramos et al., 1997 ex Mac Lean et al., 1946 Collins et al., 1983
<i>Arcanobacterium hippocoleae</i>	CCUG 44697 = CIP 106850	Vaginal discharge, horse	Hoyles et al., 2002
<i>Arcanobacterium phocae</i>	CIP 105740 = DSM 10002	Various tissues and body fluids, gray seal and common seal	Pascual Ramos et al., 1997
<i>Arcanobacterium plurinimalium</i>	CCUG 42575 = DSM 13483	Dead harbor porpoise, dead fallow deer	Lawson et al., 2001
<i>Arcanobacterium pyogenes</i>	ATCC 19411 = (NCTC 5224, CCUG 13230) = DSM 20630	Various pyogenic infections, blood, abscesses, respiratory specimens, domestic animals, humans	Glage, 1903 Pascual Ramos et al., 1997
<i>Mobiluncus</i>			
<i>Mobiluncus curtisii</i> subsp. <i>curtisii</i>	ATCC 35241 = CCUG 21018	Vaginal secretions from patients with bacterial vaginosis	Spiegel and Roberts, 1984
<i>Mobiluncus curtisii</i> subsp. <i>holmesii</i>	ATCC 35242 = CCUG 17762	Vaginal secretions from patients with bacterial vaginosis	Spiegel and Roberts, 1984
<i>Mobiluncus mulieris</i>	ATCC 35243 = CCUG 20071	Vaginal secretions, human	Spiegel and Roberts, 1984
<i>Varibaculum</i>			
<i>Varibaculum cambriense</i>	CCUG 44998 = CIP 107344	Clinical sources including breast, brain, cheek, submandibular, postauricular, and ischioanal abscesses and intrauterine contraceptive devices, human	Hall et al., 2003

of the family Actinomycetaceae. Phylogenetic trees have been included in various publications covering descriptions of novel species and phylogenetic analyses. As does the size of databases, selection of organisms of the family, outgroup organisms, and treeing algorithms differ in these surveys, and the phylogenetic trees also differ from each other in the intrafamily structure and position of the family within the suborder Actinomycineae (Stackebrandt et al., 1997). The interpretation of relatedness at the intrafamily level is based on the maximum-likelihood algorithm (ML; Fig. 1), included in the Phylip V version of Felsenstein (1993). As compared to the neighbor-joining dendrogram (Felsenstein, 1993) and the distance matrix tree of De Soete (1983), this tree is similar, though not identical, in the order of branching points of main lineages and in details of branching patterns within individual lineages (not shown). The consensus tree (Felsenstein, 1993) differs significantly from any of these trees. The term “cluster” will be used for lineages which appear to be distantly related to each other in Fig. 1, though the definition of cluster is objective.

Position at the Suborder Level

On the basis of both the phylogenetic position of type strains of species available in 1997 and on signature nucleotides of the 16S rRNA gene sequences, Stackebrandt et al. (1997) described the suborder Actinomycineae for the family Actinomycetaceae that branched between the suborders Micrococcineae and Corynebacterineae. According to the phylogenetic dendrogram generated by the ARB program, the family branches adjacent to the Bifidobacteriaceae, while the Ribosomal Database Project (http://rdp.cme.msu.edu/download/SSU_rRNA/SSU_Prok.phylo) groups the Actinomycetaceae with the Micrococcineae and the Bifidobacteriaceae (subdivision 2.30.1.9.2). In the description of *Arcanobacterium* (Pascual Ramos et al., 1997b), the Actinomycetaceae branched next to the

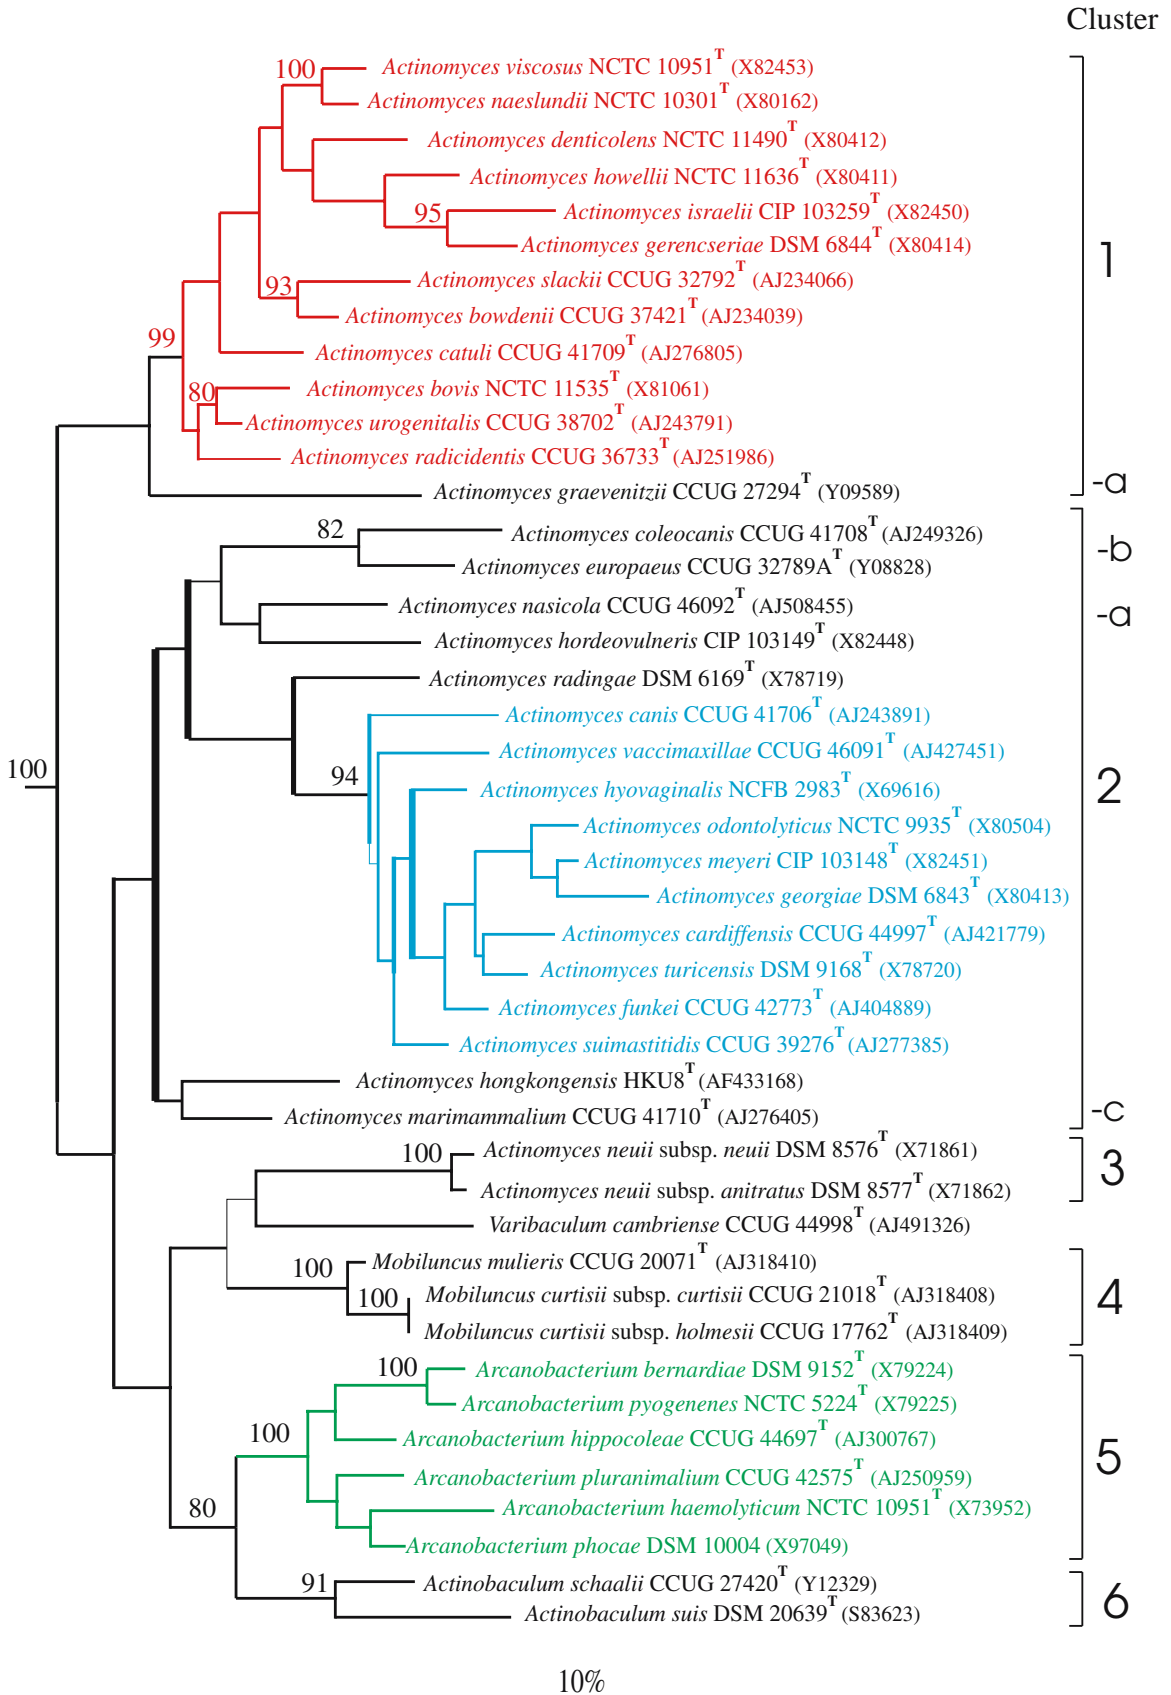

Micrococcineae (only two sequences included) and Propionibacterineae.

Intrafamily Relatedness

Similarity values of 16S rRNA gene sequence analyses for members of the family range from 88% to 99%, indicating the presence of several phylogenetically defined clusters (Fig. 1), which are separated by intra-cluster similarity values ranging from 88–90% to 89–92%. The idea that the genus *Actinomyces* may not represent a monophyletic taxon has been expressed before by Pascual Ramos et al. (1997b). Because of the lack of phenotypic and chemotaxonomic properties that support a taxonomic dissection of the family, the family serves as a phylogenetic dumping ground. Chemotaxonomic properties, demonstrated to correlate well with phylogenetic structure in other actinobacterial genera, are either not available or not exclusive in phylogenetic clusters. Although tempting, a purely phylogeny based dissection is not favored, as novel sequences may blur the present topology of the family.

Three clusters correspond to *Mobiluncus*, *Arcanobacterium* and *Actinobaculum*, respectively. The latter two genera are phylogenetic neighbors, while *Mobiluncus* species branch adjacent to *Actinomyces neuui*. From a phylogenetic point of view, members of *Mobiluncus*, *Arcanobacterium* and *Actinobaculum* appear to have originated as descendants of an *Actinomyces* ancestor, but even this situation may change with inclusion of more sequences.

Members of *Actinomyces* form several phylogenetic clusters, the number of which depends on the cut-off branching points. As the branching is rarely supported by high bootstrap values, the level at which these clusters are considered taxonomically coherent entities should be decided on the basis of results of taxonomic investigations, e.g., chemotaxonomy, physiology and morphology. Even within individual clusters, the majority of species are remotely related, only showing more than 3% dissimilarity between their 16S rRNA gene sequences. Following the

suggestion of Stackebrandt and Goebel (1994), that at this low level of relatedness DNA-DNA hybridization would result in values significantly below the species delineation threshold value of around 70% (Wayne et al., 1987), most authors refrained from confirming the species status of the more recently described species by applying this technique to the type strains of the novel species.

On the basis of similar cut off points, *Actinomyces* species (excluding *A. neuui*) form two major clusters. Cluster 1 contains either 11 or 13 species, depending on whether *A. graevenitzii* and *A. radidentis* are included or whether they represent individual lineages. On the basis of 16S rRNA gene signature nucleotides (Table 4), *A. radidentis* should be considered a member of cluster 1, whereas *A. graevenitzii* shows deviations from the set of signature nucleotides and should be treated as a separate phylogenetic unit. The remaining *Actinomyces* species (except for *A. neuui*) form cluster 2. While the majority of species of cluster 2 are moderately related, four distantly related subclusters emerge, containing *A. radingae*, *A. marimammalium*, *A. hongkongensis*, *A. europaeus* and *A. coleocanis*, as well as *A. nasicola* and *A. hordeovulneris*, respectively. The individual lineages are defined by the signature nucleotides shown in Table 4.

Description of the Phylogenetic Clusters and Subclusters

CLUSTER 1, CORE CLUSTER 1 Members of core cluster 1, sharing 94–99% sequence similarity, can be considered authentic *Actinomyces* species as it contains the type species *A. bovis*. This species is closely related to *A. urogenitalis* (97.9% similarity; 93% bootstrap value) as originally pointed out in the description of this species (Nikolaitchouk et al., 2000). Additional pairs of phylogenetic neighbors are *A. israelii* and *A. gerencseriae* (96.8%, 95% bootstrap value), *A. slackii* and *A. bowdenii* (97.3%, 93% bootstrap value), and *A. viscosus* and *A. naeslundii* (99.2%, 100% bootstrap value). All other species form individual lines of descent. Results of DNA-DNA reassociation experiments, determined by the S1 nuclease method (Johnson et al., 1990) and the membrane filter hybridization method (Dent and Williams, 1984b), indicated that

A. israelii, *A. gerencseriae*, *A. denticolens*, *A. naeslundii* and *A. viscosus* constituted genomically well-separated species. The relatedness among the latter two species was higher than that found for the other species. *Actinomyces gerencseriae* (ATCC 23860^T), formerly treated as a strain of *A. israelii* serovar 2, was identified as a taxon separate from *A. israelii* serovar 1 strains by oligonucleotide probing (Stackebrandt and Charfreitag, 1990) and low DNA reassociation values (Johnson et al., 1990).

CLUSTER 1A The distinct phylogenetic position of *A. graevenitzii*, sharing less than 94% 16S rRNA gene sequence similarity with other species of the genus (Pascual Ramos et al., 1997a) has been verified in subsequent descriptions of new *Actinomyces* species (Pascual et al., 1999; Nikolaitchouk et al., 2000; Hoyles et al., 2001a; Hoyles et al., 2001b; Hoyles et al., 2001c; Hoyles et al., 2002a). In these dendrograms, *A. graevenitzii* constituted the deepest branch of core cluster 2, or it branched off even deeper, giving the appearance of an isolated phylogenetic lineage within *Actinomyces*. The branching point of the *A. graevenitzii* lineage is supported by a 99% bootstrap value. The 16S rRNA gene sequence of the type strain CCUG 27294^T (www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=nucleotide&search=27294) contained several undetermined nucleotides, erroneous stretches and deletions. The corrected sequence (A. F. Yassin, unpublished data) changed neither the similarity values nor its branching point but supported the distinct signature of the organism.

CLUSTER 2, CORE CLUSTER 2 Except for *A. odontolyticus*, *A. meyeri* and *A. georgiae* described in 1958, 1984 and 1990, respectively, this cluster, supported by high statistical significance (94% bootstrap value), contains species that have been described within the past 10 years. Some species pairs are moderately related, e.g., *A. suimastiditis* and *A. hyovaginalis* (97.3% similarity), *A. cardiffensis* and *A. turicensis*, as well as *A. meyeri* and *A. odontolyticus*. Together with their phylogenetic neighbor *A. georgiae* (97.7%), the latter two species have been subjected to DNA-DNA reassociation studies (Johnson et al., 1990); low hybridization values confirmed their separate species status.

Fig. 1. Neighbor-joining tree (Felsenstein, 1993) of 16S rRNA gene sequences displaying the relationship of members of the family Actinomycetaceae. Numbers at branch points refer to bootstrap values (500 resamplings). This dendrogram differs in details from previously published dendrograms of novel species of individual actinomycete genera to the same extent as the latter dendrograms differ from each other. This can be explained by differences in the number and identity of the reference organisms included, which may significantly influence the topology of branching patterns. Scale bar: 10% sequence divergence. The designation of clusters on the right margin was solely based on phylogenetic grounds.

Table 3. List of synonyms and basonyms of species of Actinomycetaceae.

Species	Synonym	Basonym

Abbreviations: V, variable nucleotide composition; Y, pyrimidine; and R, purine.

^aA signature is defined as the presence of a nucleotide unique in members (>90%) of a single cluster or more clusters but not in all clusters of the family.^bContains *A. radidentis*.^cContains *A. canis*.

The 16S rRNA gene sequence similarity values found between *A. canis* and members of the core cluster 2 are 93.1–96.6%. Its separate phylogenetic position as a deep branching lineage of core cluster 2 organisms is in accord with the original description of Hoyles et al. (2000). The major deviation from the set of signatures defining core cluster 2 sequences is a stretch of 3 base pairs (positions 614–626, 615–625, and 616–624).

Actinomyces radingae is another remote relative of cluster 2, but the branching point of this lineage is not supported by a high bootstrap value. This is in contrast to the dendrogram shown by Pascual Ramos et al. (1997b), but the number of species included is smaller than that shown in Fig. 1. As the set of signature nucleotides (Table 4) is similar to that of other members of the cluster, *A. radingae* will be considered a tentative member of cluster 2.

CLUSTER 2A—*A. HORDEOVULNERIS* AND *A. NASICOLA* The phylogenetic position of *A. hordeovulneris* was not investigated in the original description of this species (Buchanan et al., 1984b) but included in the broad phylogenetic survey of the genus by Pascual Ramos et al. (1997b). The isolated position of this species has been seen since then in many subsequent publications of *Actinomyces* species. Several deviations in the set of 16S rRNA gene sequence signatures of cluster 2 support the branching point of *A. hordeovulneris*. The species *A. nasicola* (Hall et al., 2003b), isolated from the nose of a human, was recently added to this lineage.

CLUSTER 2B—*A. EUROPAEUS* AND *A. COLEOCANIS* These two species share a remote relationship of 94.2% sequence similarity. The branching point of this lineage is not settled, as seen by low bootstrap values and different affiliations of either one or both species in dendrograms published in recent species descriptions (Pascual et al., 1999; Collins et al., 2000b; Hoyles et al., 2000; Hoyles et al., 2001c; Hoyles et al., 2002a; Nikolaitchouk et al., 2000). The presence of unique 16S rRNA gene nucleotide signatures (Table 4), shared specifically with members of other clusters, highlights the separate phylogenetic position of these two organisms. Affiliation to cluster 2 should be regarded as tentative.

CLUSTER 2C—*A. MARIMAMMALIUM* AND *A. HONGKONGENSIS* *Actinomyces marimammalium* and the recently described *A. hongkongensis* (Woo et al., 2003) branch deeply within the tree of Actinomycetaceae species, showing almost equidistant relationship to members of other clusters. The bootstrap value for the two type strains of this cluster is low. The signature nucleotides (Table 4) of *A. marimammalium* support

the isolated phylogenetic position. Affiliation to cluster 2 should be regarded as tentative.

CLUSTER 3—*ACTINOMYCES NEUII* AND *VARIBACULUM CAMBRIENSE* *Actinomyces neuui* (Funke et al., 1994) was described at a time when the phylogenetic diversity of the genus *Actinomyces* was not apparent. Since then, the separate position of the species, apart from other members of the genus, has been noted, but lack of distinct and differentiating phenotypic properties has hindered the formal description of a new genus for the former CDC group 1 (subspecies *neuui*) and CDC group 1-like coryneforms (subspecies *anitratus*). The two groups were considered subspecies because of phenotypic differences observed for the phylogenetically highly related type strains (99.7% sequence similarity). Nonquantitative DNA–DNA hybridization (Funke et al., 1993), however, indicated a low degree of overall genomic relatedness between members of the two subspecies. The branching of *Varibaculum cambriense* to the *A. neuui* lineage is without statistical significance.

CLUSTER 4—*MOBILUNCUS* Formerly considered a member of the Bacteroidaceae (Spiegel and Roberts, 1984a), the genus was transferred to the Actinomycetales by Lassnig et al. (1989) on the basis of 16S rRNA gene sequence analyses. The phylogenetic closeness between *Mobiluncus* and *Actinomyces* species became apparent, but only a few species of core cluster 1 were available for comparison. Similarities were found in the end products of carbohydrate fermentation and a requirement for CO₂, but one of the salient properties excluding reclassification of *Mobiluncus* species as species of *Actinomyces* was the low DNA mol% G+C content of only 49–52. In the past years, improved sequences have been published (Tiveljung et al., 1995) or submitted to public databases (L. Hoyles, unpublished data), but the branching of *Mobiluncus* within the radiation of the family Actinomycetaceae did not change. The phylogenetic coherence of *Mobiluncus* species and the significance of the topology of the branching pattern are supported by 16S rRNA gene sequence signatures. Though also depicted in the dendrograms published by Funke et al. (1997a), Nikolaitchouk et al. (2000), Collins et al. (1993), and Hoyles et al. (2001a), the branching of the genus *Mobiluncus* next to *Actinomyces neuui* is barely of statistical significance.

CLUSTER 5—*ARCANOBACTERIUM* This genus was established for the reclassified species “*Corynebacterium haemolyticum*” (Collins et al., 1982c). Later, *A. pyogenes*, *A. bernardiae*, *A. phocae*, *A.*

pluranimalium and *A. hippocoleae* (Pascual Ramos et al., 1997b; Lawson et al., 2001a; Hoyles et al., 2002b) were added to the genus. The phylogenetic topology (Fig. 1) agrees with that shown by Hoyles et al. (2002b). The phylogenetic coherency of the genus is supported by a set of distinct signature nucleotides. The position of *Arcanobacterium* species, adjacent to members of *Actinobaculum*, supports earlier reports in the more recent descriptions of *Actinomyces*, *Arcanobacterium* and *Actinobaculum* species.
